Abstract

Last decades have witnessed a number of studies devoted to multi-view learning algorithms, however, few efforts have been made to handle online multi-view learning scenarios. In this paper, we propose an online Bayesian multi-view learning algorithm to learn predictive subspace with max-margin principle. Specifically, we first define the latent margin loss for classification in the subspace, and then cast the learning problem into a variational Bayesian framework by exploiting the pseudo-likelihood and data augmentation idea. With the variational approximate posterior inferred from the past samples, we can naturally combine historical knowledge with new arrival data, in a Bayesian Passive-Aggressive style. Experiments on various classification tasks show that our model have superior performance.

1 Introduction

Nowadays, multi-view data are often generated from multiple information channels continuously, e.g., hundreds of YouTube videos consisting of visual, audio and text features are uploaded every minute. Multi-view learning arouses amounts of interests in the past decades [Blum and Mitchell, 1998; Yarowsky, 1995; Gönen and Alpaydın, 2011; Quang et al., 2013; Sun and Chao, 2013]. Among them, the multi-view subspace learning approaches aim at obtaining a subspace shared by multiple views and then learning models in the shared subspace [Sharma et al., 2012; Hardoon et al., 2004; Guo and Xiao, 2012]. They are very useful for cross-view classification and retrieval. However, these approaches are prone to overfitting to small training data without considering the maximum margin principle. In [Chen et al., 2012], a large-margin harmonium model (MMH) based on latent subspace Markov network is developed for multi-view data. But MMH is under the maximum entropy discrimination framework and cannot infer the penalty parameter of max-margin models in Bayesian style automatically. In [Du et al., 2015], a posterior-regularized Bayesian approach is proposed to combine Principal Component Analysis (PCA) with the max-margin learning, which can infer the penalty parameter of max-margin models but cannot address multi-view data.

On the other hand, multi-view data often cannot be collected in a single time due to temporal and spatial constraints in applications, while the traditional multi-view algorithm need store the entire training samples. Online learning is an efficient method to address this problem. Many efforts have been made on the studies of online learning [Cesa-Bianchi and Lugosi, 2006; Hazan et al., 2007; Chechik et al., 2010]. Unfortunately, there are few studies about online multi-view learning. OPMV is one of the few online multi-view learning [Zhu et al., 2015]. OPMV is not in a Bayesian framework and does not introduce the max-margin principle, thus it is prone to overfitting to small training data. And OPMV is formulated as a point estimate by optimizing some deterministic objective function. Online Passive-Aggressive (PA) learning provides a method for online large-margin learning [Crammer et al., 2006]. Although it enjoys strong discriminative ability suitable for predictive tasks, it is also formulated as a point estimate by optimizing some deterministic objective function. The point estimate can be affected seriously by inappropriate regularization, outliers and noises, especially when the training data arrive sequentially. Based on the online PA learning, Shi proposes a Bayesian PA learning method [Shi and Zhu, 2013] which infers a posterior under the Bayesian framework instead of a point estimate. Nevertheless, these online learning methods cannot process multi-view data. To the best of our knowledge, there has been few efforts focused on online multi-view learning under the Bayesian framework.

In this paper, we address the aforementioned problems by developing an online Bayesian multi-view subspace learning method with max-margin principle. Specifically, we first propose a predictive subspace learning method based on factor analysis and define a latent margin loss for classification in the subspace. Then we cast the learning problem into a variational Bayesian framework by exploiting the pseudo-likelihood and data augmentation idea which allows us to automatically infer the penalty parameter. With the variational approximate posterior inferred from the past samples, we can naturally combine historical knowledge with new arriving data, in a Bayesian Passive-Aggressive style. We up-
date our model with the training data coming one by one, instead of storing all training data. Experiments on synthetic and various real classification tasks show both our batch and online model have superior performance, compared with a number of competitors.

Related Work
The earliest works of multi-view learning are introduced by Blum and Mitchell [Blum and Mitchell, 1998] and Yarowsky [Yarowsky, 1995]. Nowadays, there are many multi-view learning approaches, e.g., multiple kernel learning [Gönen and Alpaydın, 2011], disagreement-based multi-view learning [Blum and Mitchell, 1998] and late fusion methods which combine outputs of the models constructed from different view features [Ye et al., 2012]. Especially, the multi-view subspace learning algorithms learn latent salient representation of multi-view data [Sharma et al., 2012; Hardoon et al., 2004]. This approach aims at obtaining a subspace shared by multiple views and then learn models in the shared subspace.

Online learning starts from the Perceptron algorithm [Rosenblatt, 1958] and has attracted much attention during the past years [Cesa-Bianchi and Lugosi, 2006; Hazan et al., 2007; Grangier and Bengio, 2008; Chechik et al., 2010]. Crammer proposes the Online Passive-Aggressive (PA) learning which provides a general framework for online large-margin learning[Crammer et al., 2006], with many applications [Chiang et al., 2008]. Online Bayesian Passive-Aggressive learning presents a generic framework of performing online learning for Bayesian max-margin models [Shi and Zhu, 2013].

2 The Model
In this section, we firstly propose the max-margin subspace learning based on factor analysis. Then we develop a multi-view classification with max-margin subspace learning under the Bayesian framework. Finally, we extend the batch model to the online scenario which trains the model with the samples coming one by one.

2.1 Max-margin Subspace Learning
Suppose we have a set of $N$ observations $x^{(n)}$, $n = 1, \cdots, N$ in $d$-dimension feature space and a $1 \times N$ label vector $y$ with its element $y_n \in \{+1, -1\}$, $n = 1, \cdots, N$. Factor analysis projects an observation into a low dimensional space that captures the latent feature of data. The generative process for the $n$-th observation $x^{(n)}$ is as follows:

$$x^{(n)} \sim \mathcal{N}(\varepsilon | 0, \Phi)$$

where $\varepsilon \in \mathbb{R}^{d \times 1}$ denotes the Gaussian noise, $\Phi \in \mathbb{R}^{d \times d}$ is a variance matrix of $\varepsilon$, $\mu \in \mathbb{R}^{d \times 1}$ is the mean value of $x^{(n)}$, $W \in \mathbb{R}^{d \times m}$ is the factor loading matrix, $z^{(n)}$ is an $m$-dimensional latent variable.

The estimates of model variables $(\mu, W, \Phi, Z)$ can be obtained as follows:

$$\max_{\mu, W, \Phi, Z} \ell(\mu, W, \Phi, Z) = \max_{\mu, W, \Phi, Z} \log \prod_{n=1}^{N} \frac{1}{(2\pi)^{d/2}|\Phi|} \cdot \exp\left(-\frac{1}{2}(x^{(n)} - \mu - Wz^{(n)})^{T}\Phi^{-1}(x^{(n)} - \mu - Wz^{(n)})\right).$$

However, factor analysis is an unsupervised model, which learns the latent variables of the observations without using any label information. The max-margin principle can be introduced to incorporate label information into the factor analysis model. We define $z = [z^T, 1]^T$ as the augmented latent representation of observation $x$, and let $f(x; \tilde{z}, \eta) = \eta^T z$ be a discriminant function parameterized by $\eta$. Now for fixed values of $Z$ and $\eta$, we can compute the margin loss on training data $(X, y)$ by

$$\ell_m(Z, \eta) = \sum_{n=1}^{N} \max(0, 1 - y_n f(x^{(n)}; \tilde{z}^{(n)}, \eta)).$$

The max-margin subspace learning model can be formulated as follows:

$$\max_{\mu, W, \Phi, Z, \eta} \ell_m(\mu, W, \Phi, Z) = C\ell_m(Z, \eta),$$

where $C$ is the regularization parameter.

2.2 Multi-view Classification with Bayesian M2SL
Then we propose a Bayesian max-margin subspace multi-view learning (BM2SMVL) model. We assume that $N_v$ is the number of views, $N_v$ is the number of classes, $d_i$ is the dimension of the $i$-th view, the data matrix of the $i$-th view is $X_i \in \mathbb{R}^{d_i \times N}$ consisting of $N$ observations $x_i^{(n)}$ in $d_i$-dimension feature space, $x_i^{(n)} = \{x_i^{(n)}\}_{i=1}^{N_v}$ denotes the $n$-th observation, and $Y$ is a $N_v \times N$ label matrix consisting of $N$ label vectors $y^{(n)} = \{y^{(n)}_c\}_{c=1}^{N_v}$.

If the $n$-th observation's label belongs to the $c$-th class, we define $y^{(n)}_c = +1$ otherwise $y^{(n)}_c = -1$.

In our BM2SMVL model, each view $x_i^{(n)}$ of the $n$-th observation $x^{(n)}$ is generated from the latent variable $z^{(n)}$. We impose prior distributions over all variables shown in Eq.(1). The generative process for the $n$-th observation is as follows:

$$z^{(n)} \sim \mathcal{N}(z^{(n)} | 0, I_m)$$

$$\mu_i \sim \mathcal{N}(\mu_i | 0, \beta_i^{-1}I_{d_i})$$

$$\alpha_i \sim \prod_{j=1}^{c} \Gamma(\alpha_i j \vert a_{\alpha_i j}, b_{\alpha_i j})$$

$$W_i | \alpha_i \sim \prod_{j=1}^{c} \mathcal{N}(w_{ij} | 0, diag(\alpha_i))$$

$$\phi_i | \phi_{\alpha_i} \sim \prod_{j=1}^{c} \mathcal{G}(\phi_{ij} \vert a_{\phi_{ij}}, b_{\phi_{ij}})$$

$$x_i^{(n)} | z^{(n)} \sim \mathcal{N}(x_i^{(n)} | W_i z^{(n)} + \mu_i, \phi_i^{-1}I_{d_i})$$

where $\Gamma(\cdot)$ is the Gamma distribution, $\beta_i, \alpha_{\alpha_i j}, b_{\alpha_i j}, a_{\phi_{ij}}, b_{\phi_{ij}}$ are the hyper-parameters, and $W_i \in \mathbb{R}^{d_i \times m}$. The prior on $W_i$ and $\alpha_i$ is introduced according to the automatic relevance determination [Reents and Urbanzicz, 1998]. In order to improve the efficiency of our algorithm, we define the variance matrix $\Phi_i$ of the $x_i^{(n)}$ as a diagonal matrix $\Phi_i^{-1}I_{d_i}$. Let $\Omega = (\mu, \alpha, W, \Phi, Z)$ denote all variables, $p_0(\Omega) = p_0(\mu)p_0(W, \alpha)p_0(\Phi)p_0(Z)$ is the prior of $\Omega$. We can verify the Bayesian posterior distribution $p(\Omega | X) = p_0(\Omega)p(X | \Omega)$ is equal to the solution of the following optimization problem:

$$\min_{\Omega \in \mathcal{P}} KL(q(\Omega) || p_0(\Omega)) = -E_{q(\Omega)}[\log p(X | \Omega)],$$

where $KL(q || p)$ is the Kullback-Leibler divergence, and $\mathcal{P}$ is the space of probability distributions. When the observations are given, $p(X)$ is a constant.
Next, we adapt our model with the one-VS-rest strategy like that for SVM for multi-class classification problems. We have $N_c$ classifiers, and take the $c$-th classification for an example: $f_c(x_t^{(n)}; z_t^{(n)}, \eta_c) = \eta_c^T z_t^{(n)}$ denotes a discriminant function. Under the Bayesian framework, we impose a prior on $\eta_c$ as follows:

$$
\nu_c \sim p_0(\nu_c) = \Gamma(a_{\nu,c}, b_{\nu,c})
$$

$$
p(\eta_c | \nu_c) = \mathcal{N}(\eta_c | 0, \nu_c^{-1} I_{(m+1)}),
$$

where $a_{\nu,c}$ and $b_{\nu,c}$ are hyper-parameters. For simplicity, let $\Theta = \{ (\eta_c, \nu_c) \}_{c=1}^{N_c}$. Then we can replace the margin loss with the expected marginal loss for the classification. We introduce

$$
\varphi(\mathbf{y}, \lambda | \mathbf{Z}, \eta) = \prod_{n=1}^{N} \prod_{c=1}^{N_c} \exp \{-2C \cdot \text{max}(0, 1 - y_c^{(n)} \eta_c^T z^{(n)}) \} \tag{5}
$$

as the pseudo-likelihood of the $n$-th data’s label variable. We can get our final model as follows:

$$
\min_{q(\Omega, \Theta) \in \mathcal{P}} KL(q(\Omega, \Theta) || p_0(\Omega, \Theta) - E_q(\Omega) \{ \log p(\mathbf{X} | \Omega) \}
$$

$$
- E_q(\Omega, \Theta) \{ \log \varphi(\mathbf{Y} | \mathbf{Z}, \eta) \}, \tag{6}
$$

where $p_0(\Omega, \Theta)$ is the prior, $p_0(\Omega, \Theta) = p_0(\Omega)p_0(\Theta)$, $p_0(\Theta,c) = p(\eta_c | \nu_c)p(\nu_c)$ and $C$ is the regularization parameter. Solving problem (6), we can get the posterior distribution

$$
q(\Omega, \Theta) = \frac{p_0(\Omega, \Theta)p(\mathbf{X} | \Omega)\varphi(\mathbf{Y} | \mathbf{Z}, \eta)}{\phi(\mathbf{X}, \mathbf{Y})}, \tag{7}
$$

where $\phi(\mathbf{X}, \mathbf{Y})$ is the normalization constant. In order to approximate $q(\Omega, \Theta)$ we use variational approximate inference which is introduced in the Section 3.

### 2.3 Online BM^2SMVL

The goal of online learning is to minimize the cumulative loss for a certain prediction task from the sequentially arriving training samples. In this section, we present an online BM^2SMVL (OBM^2SMVL) based on the online Passive-Aggressive learning framework [Crammer et al., 2006]. This generic framework for online large-margin learning has been used in many applications [Chiang et al., 2008]. Online Bayesian Passive-Aggressive learning was presented for online large-margin learning has been used in many applications [Crammer et al., 2006].

Assuming we have already got the posterior $q(t; \Omega, \Theta)$ at time $t$, when a new data $(x_t^{(t+1)}, y_t^{(t+1)})$ is coming, we need update the new posterior distribution $q_{t+1}(\Omega, \Theta)$. For simplicity, we define $\omega$ as the parameterized model and $\ell(\omega; x_t^{(t+1)}, y_t^{(t+1)})$ as the loss for the new data $(x_t^{(t+1)}, y_t^{(t+1)})$. Our OBM^2SMVL sequentially infers a new posterior distribution $q_{t+1}(\omega)$ on the arrival of new data $(x_t^{(t+1)}, y_t^{(t+1)})$ by solving the following optimization problem:

$$
\min_{q(\omega) \in \mathcal{P}} KL(q(\omega) || q_t(\omega)) - E_{q(\omega)} \{ \log p(\mathbf{x}_t^{(t+1)} | \omega) \}
$$

$$
+ \ell(\omega; x_t^{(t+1)}, y_t^{(t+1)}).
$$

The online model includes three main updating rule. Firstly, we hope KL$(q(\omega) || q_t(\omega))$ is as small as possible. It means that $q_t(\omega)$ is close to $q_t(\omega)$. Secondly, the likelihood of the new data $E_{q(\omega)} \{ \log p(\mathbf{x}_t^{(t+1)} | \omega) \}$ is high enough. Thirdly, the loss of the new data $\ell(\omega; x_t^{(t+1)}, y_t^{(t+1)})$ is as small as possible. It means that the new model $q_t(\omega)$ suffers little loss from the new data.

To introduce the online idea to the above multi-view classification BM^2SMVL, we let $(\Omega, \Theta)$ denote $\omega$. A new posterior distribution $q_{t+1}(\Omega, \Theta)$ on the arrival of new data $(x_t^{(t+1)}, y_t^{(t+1)})$ can be gotten by solving the following optimization problem:

$$
\min_{q(\Omega, \Theta) \in \mathcal{P}} KL(q(\Omega, \Theta) || q_t(\Omega, \Theta)) - E_{q(\Omega, \Theta)} \{ \log p(\mathbf{x}_t^{(t+1)} | \Omega, \Theta) \}
$$

$$
+ \ell(\Omega, \Theta; x_t^{(t+1)}, y_t^{(t+1)}).
$$

As above, we introduce $\varphi(\cdot)$ function to replace the hinge loss as the pseudo-likelihood. So the formula is replaced by:

$$
\min_{q(\Omega, \Theta) \in \mathcal{P}} KL(q(\Omega, \Theta) || q_t(\Omega, \Theta)) - E_{q(\Omega, \Theta)} \{ \log p(\mathbf{x}_t^{(t+1)} | \Omega, \Theta) \}
$$

$$
- E_{q(\Omega, \Theta)} \{ \log \varphi(\mathbf{y}_t^{(t+1)} | \mathbf{Z}_t^{(t+1)}, \eta) \}.
$$

Similar to Eq.(7), we can get the posterior distribution:

$$
q_{t+1}(\Omega, \Theta) = \frac{q_t(\Omega, \Theta)p(\mathbf{x}_t^{(t+1)} | \Omega)\varphi(\mathbf{y}_t^{(t+1)} | \mathbf{Z}_t^{(t+1)}, \eta)}{\phi(\mathbf{x}_t^{(t+1)}, \mathbf{y}_t^{(t+1)})},
$$

where $\phi(\mathbf{x}_t^{(t+1)}, \mathbf{y}_t^{(t+1)})$ is the normalization constant. Note that, the latent variable $\mathbf{z}_t^{(t)}$ is unrelated to the new posterior, because the variable $\mathbf{z}_t^{(t+1)}$'s prior is $p_0(\mathbf{z}_t)$. Let $(\Omega, \Theta, \mathbf{z}_t^{(t)})$ denote all variables in $\Omega$ and $\Theta$ except $\mathbf{z}_t^{(t)}$, then we can further get

$$
q_{t+1}(\Omega, \Theta) = \frac{q_t(\Omega, \Theta | \mathbf{z}_t^{(t)})p_0(\mathbf{z}_t)p(\mathbf{x}_t^{(t+1)} | \Omega)}{\phi(\mathbf{x}_t^{(t+1)}, \mathbf{y}_t^{(t+1)})}.\tag{8}
$$

In order to approximate $q_{t+1}(\Omega, \Theta)$ we use variational approximate inference which is introduced in Section 3.

### 3 Variational Inference

Because the posterior is intractable to compute, we apply the variational inference method [Beal, 2003] to approximate the posteriors in (7) for BM^2SMVL and in (8) for OBM^2SMVL. This method is much more efficient than sampling based methods [Gilks, 2005].

#### 3.1 Data Augmentation

Since the pseudo-likelihood function $\varphi(\cdot)$ involves a max operator which is difficult and inefficient for posterior inference. We re-express the pseudo-likelihood function into the integration of a function with augmented variable based on the data augmentation idea [Polson and Scott, 2011]. For BM^2SMVL, we replace the pseudo-likelihood $\varphi(\cdot)$ with:

$$
\varphi(y_c^{(n)} | \mathbf{z}_c^{(n)}, \eta_c) =
$$

$$
\int_0^{\infty} \exp \left\{ -\frac{1}{2\lambda_c^{(n)}} [\lambda_c^{(n)} + C(1 - y_c^{(n)}) \eta_c^T \mathbf{z}_c^{(n)}]^2 \right\} \cdot \frac{d\lambda_c^{(n)}}{\sqrt{2\pi\lambda_c^{(n)}}}.
$$
Then we can get
\[
\varphi(Y, \lambda | Z, \eta) = \prod_{n=1}^{N} \prod_{c=1}^{N_c} \frac{\exp\left\{ -\frac{1}{2\lambda^{(n)}} (\lambda^{(n)}_{c} + C(1 - y_n^T \eta_c^T z^{(n)})^2) \right\}}{\sqrt{2\pi} \lambda^{(n)}_{c}}.
\]
Similarly, we introduce the augmented variable to the pseudo-likelihood function \( \varphi(\cdot) \) for OBM²SMVL:
\[
\varphi(y^{(t+1)}, \lambda^{(t+1)} | z^{(t+1)}, \eta) = \prod_{c=1}^{N_c} \frac{\exp\left\{ -\frac{1}{2\lambda^{(t+1)}_{c}} (\lambda^{(t+1)}_{c} + C(1 - y^{(t+1)}_{c} \eta_c^T z^{(t+1)})^2) \right\}}{\sqrt{2\pi} \lambda^{(t+1)}_{c}}.
\]

### 3.2 Variational Approximate Inference

Next, we apply the mean-field variational method to approximating the posterior distributions.

#### Variational Inference in BM²SMVL

Firstly, we define a family of factorized but free-form variational distributions:
\[
V(\Omega, \Theta, \lambda) = V(\mu)V(W)V(\alpha)V(\phi)V(Z)V(\eta)V(\lambda)V(\nu).
\]

The main idea of variational Bayesian inference is that we need to minimize the KL divergence KL(V(\Omega, \Theta, \lambda)||g(\Omega, \Theta, \lambda)) between the approximating distribution and the target posterior. Next, we initialize the distributions of V(\Omega, \Theta, \lambda). Then we iteratively update parameter of our model by fix other parameters as the current estimates. Now, we give the joint distribution of data and parameters:
\[
p(\Omega, \Theta, \lambda, X, Y) = p_0(\mu)p(W|\alpha)p_0(\alpha)p_0(\phi)p_0(Z)p(\eta|\nu) \\
\cdot p_0(\nu)p(X|\mu, W, \phi, Z)\varphi(Y, \lambda, Z, \eta).
\]

It can be shown that when keeping all other factors fixed the optimal distribution \( V^*(\lambda) \) satisfies
\[
V^*(\lambda) \propto \exp\{E_{-\lambda}[\log p(\Omega, \Theta, \lambda, X, Y)]\},
\]
where \( E_{-\lambda} \) denotes the expectation with respect to \( V(\Omega, \Theta, \lambda) \) over all variables except for \( \lambda \). Then we can get the updating formula for \( E_{-\lambda} \):
\[
V^*(\lambda) = \prod_{c=1}^{N_c} \prod_{n=1}^{N} GIG(\lambda^{(n)}_{c} + \frac{1}{2}, 1, \lambda^{(n)}_{c})
\]
\[
\lambda^{(n)}_{c} = C^2 ((1 - y^{(n)}_{c} \eta_c^T z^{(n)})^2),
\]
where \( \cdot \) represents the expectation, GIG(\cdot) is the generalized inverse Gaussian distribution. Similarly, we can get the updating formulas for all other factors. Since they are tedious and easy to derive, here we only provide the equations for \( Z \), other updating formulas are omitted because of the limited space of the paper,
\[
V^*(Z) = \prod_{n=1}^{N} \mathcal{N}(z^{(n)} | \mu^{(n)}_{\lambda}, \Sigma^{(n)}_{\lambda})
\]
\[
\Sigma^{(n)}_{\lambda} = \left\{ C^2 \sum_{c=1}^{N_c} (\tilde{\eta}_c \tilde{\eta}_c^T) \mathcal{N}(\lambda^{(n)}_{c})^{-1} + I_m \\
+ \sum_{i=1}^{N_c} \langle \phi_i \rangle (W_i^T W_i) \right\}^{-1}
\]
\[
\mu^{(n)}_{\lambda} = \left\{ C^2 \sum_{c=1}^{N_c} (\tilde{\eta}_c \tilde{\eta}_c^T) \mathcal{N}(\lambda^{(n)}_{c})^{-1} + (\mu_i) \\
+ \sum_{i=1}^{N_c} \{ C + (\mathcal{N}(\lambda^{(n)}_{c})^{-1}) y^{(n)}_{i} (\tilde{\eta}_c) \\
- C^2 ((\lambda^{(n)}_{c})^{-1}) y^{(n)}_{i} (\tilde{\eta}_c) \} \right\} \eta^{(n)}_{c},
\]
where \( \tilde{\eta}_c \) denotes the first \( m \) dimensions of \( \eta_c \), i.e., \( \eta_c = [\tilde{\eta}_c, \eta_{c,(m+1)}] \).
3.3 Computational Complexity

For each iteration of parameter updating in our batch learning BM²SMVL, we need \(O(N_v d_m n^2)\) computation, where \(d\) is the average dimension of all \(N_v\) views. The most computation is spent on the calculation of \(\Sigma_{z(n)}\), \(n = 1, \cdots, N\) where the matrix multiplication \((W_i^1W_i^3)\) consumes \(d_m m^2\) computation. And each iteration of parameter updating in our online learning OBMSMV consumes \(O(N_v d_m n^2)\) when a new sample is coming.

4 Experiments

We evaluate the proposed batch learning model BM²SMVL and online learning model OBMSMV on various classification tasks including image data and text data.

4.1 Real Data Sets

There are four data sets, i.e., Trecvid, Washington, Cornell and News4Gv, used in our experiments. Trecvid contains 1,078 manually labeled video shots that belong to five categories [Chen et al., 2012]. Each shot is represented by a 1,894-dim binary vector of text features and a 165-dim vector of HSV color histogram. WebKB data set has two views, including the content features of the web pages and the link features exploited from the link structures. This data set consists of 877 web pages from computer science departments in four universities, i.e., Cornell, Washington, Wisconsin and Texas. And each university has five document classes, i.e., course, faculty, student, project and staff. We select the web pages from Cornell and Washington as our experimental data¹. These two data sets have five classes with two views. 20Newsgroups data set is widely used for classification tasks including image data and text data.

4.2 Competitors

We compare our model with five competitors:

- **VMRML** [Quang et al., 2013]: it is a vector-valued manifold regularization multi-view learning. The regularization parameters are set as the default value in their paper, and we tune the parameter \(\sigma\) for ‘rbf’ carefully in each data set;
- **MMH** [Chen et al., 2012]: it is a large-margin predictive latent subspace learning for multi-view data. Based on the parameters given in its code², we tune the parameters carefully to choose the best parameters for each data set;
- **SVM-FULL**: it concatenates all views to form a new single view, and applies SVM for classification. We choose the linear kernel and execute 5-fold cross-validation on training sets to decide the cost parameter \(c\) from \(10^{[-3,3]}\);
- **OPMV** [Zhu et al., 2015]: it is an online multi-view learning. According to the paper, the learning rate parameter is chose from \(2^{[-8,8]}\), the regularization parameter are chose from \(10^{[-10,0]}\), and the penalty parameters are pre-defined as 1. The parameters are set according to the above rules.

4.3 Parameter Setting

In our batch learning, the regularization parameter \(C\) is chosen from the integer set \(\{1, 2, 3\}\) and the subspace dimension \(m\) from the integer set \(\{20, 30, 50\}\) for each data set by performing 5-fold cross validation on training data. While in our online learning, the regularization parameter \(C\) is chosen from the integer set \(\{1, 5, 15\}\) and the subspace dimension \(m\) from the integer set \(\{20, 30, 50\}\). For the rest parameters, both our batch and online learning are set as the same, i.e., \(a_\alpha = b_\alpha = 1e-3\), \(a_\phi = 1e-2\), \(a_\nu = 1e-1\), \(b_\phi = b_\nu = \beta = 1e-5\).

4.4 Experimental Results

Since a normal prior with zero mean is imposed on the observation data, we normalize the observation data to have zero

mean and unit variance. In batch learning experiments, we use the same training/testing split of the TreCvid data set as in [Chen et al., 2012]. So there is only one result in this data set. For other data sets the results of all models are averaged over 20 independent runs and. All the results are shown in Table 2. The ratio sampled for training data is 0.5 in the three data set TreCvid, Washington and Cornell, and 0.05 in News4Gv. Since MMH can not address high dimensional data, e.g., News4Gv, so its result is missing for News4Gv in Table 2.

In online learning experiments, we use the same training/testing split of the above batch learning experiments. We sample 0.1 of the training data as the batch training, and the rest come one by one. Since OPMV can only deal with two-view data, so its result is missing for News4Gv in Table 3. From Table 2 and Table 3, we have the following insightful observations:

- Our BM²SMVL achieves the best performance on the TreCvid, Washington and Cornell data sets and performs just a little worse than the SVM-FULL in the News4Gv data. We attribute it to that our method can automatically infer the penalty parameter of max-margin model based on the data augmentation idea, while VMRML and MMH are both under the maximum entropy discrimination framework and cannot infer the penalty parameter. SVM-FULL makes full use of all the information from the observations by concatenating all views to form a new single view. This maybe the reason why it performs better than our BM²SMVL in the News4Gv. But some information from the observations is not helpful for the classification in other data sets. In this case, SVM-FULL cannot achieve a good performance.

- Our method infers a posterior under the Bayesian framework instead of a point estimate as in VMRML. With Baysian model averaging over the posterior, we can make more robust predictions than VMRML.

- We also find that OBM²SMVL performs better than OPMV on all data sets and just a little worse than BM²SMVL. Unlike OPMV, which seeks a point estimate by optimizing some deterministic objective function, our online model infers a posterior under the Bayesian framework. The point estimate can be affected seriously by inappropriate regularization, outliers and noises, especially when the training data arrive sequentially.

4.5 Sensitivity Analysis

We study the sensitivity of BM²SMVL and OBM²SMVL with respect to the subspace dimension $m$, and the regularization parameter $C$.

When we study the influence of $m$, $C$ (batch) is set as 2 for BM²SMVL and $C$ (online) is set as 15 for OBM²SMVL. The averaged results are shown in Figure 1 (a) and Figure 2 (a). We find that the test accuracy increases when $m$ becomes larger. And when $m$ is large enough, the test accuracy remains stable.

When we study the influence of $C$, $m$ is set as 30 for both batch and online learning. From the results in Figure 1 (b) and Figure 2 (b), we can find that different data sets may prefer different values of $C$. In batch learning, $C$ (batch) balances the classification model and subspace learning model, so our model cannot get the best performance when $C$ (batch) is too large or too small. $C$ (online) reflects the importance of new arrival data in our online model. When $C$ (online) is too small, the new arrival data plays a tiny role in the online model and offers little help to improve the performance of our online model. For some data sets like Cornell, when $C$ (online) is too large, the performance of OBM²SMVL would become bad because the online model doesn’t take full advantage of the historical knowledge. For some other data sets like TreCvid and Washington, they are less sensitive to $C$ (online) when $C$ (online) is large enough.

5 Conclusion

We propose an online Bayesian method to learn predictive subspace for multi-view data. Specifically, the proposed method is based on the data augmentation idea for max-margin learning, which allows us to automatically infer the weight and penalty parameter and find the most appropriate predictive subspace simultaneously under the Bayesian framework. Experiments on various classification tasks show that both our batch model BM²SMVL and online model OBM²SMVL can achieve superior performance, compared with a number of state-of-the-art competitors.
