Abstract

The Databionic swarm (DBS) is a flexible and robust clustering framework that consists of three independent modules: swarm based projection, high-dimensional data visualization and representation guided clustering. The first module is the parameter-free projection method Pswarm, which exploits concepts of self-organization and emergence, game theory, and swarm intelligence. The second module is a parameter-free high-dimensional data visualization technique called topographic map. It uses the generalized U-matrix, which enables to estimate first, if any cluster tendency exists and second, the estimation of the number of clusters. The third module offers a clustering method which can be verified by the visualization and vice versa. Benchmarking w.r.t. conventional algorithms demonstrated that DBS can outperform them. Several applications showed that cluster structures provided by DBS are meaningful. Exemplary, a clustering of worldwide country-related data w.r.t. the COVID-19 pandemic is presented here. Code and data is made available via open source.

1 Introduction

The term knowledge discovery refers to the general process of finding valid, novel, potentially useful, and understandable patterns in data [Fayyad et al., 1996]. Our focus lies on data-driven methods that find patterns in data that identify homogeneous groups of objects if these objects are heterogeneous between the groups or so-called clusters [Bonnier, 1964]. In this sense, cluster analysis can be seen as one step in the knowledge discovery process, and the clusters are often specified as “natural” clusters [Duda et al., 2001; Theodoridis and Koutrombas, 2009]. The question that arises is how to recognize structures that define clusters in high-dimensional data without access to prior knowledge. Typically, clustering algorithms use a global objective function which implicitly assumes specific cluster structures in data [Duda et al., 2001; Everitt et al., 2001; Handl et al., 2005; Theodoridis and Koutrombas, 2009; Ultsch and Lötšch, 2017]. Moreover, cluster analysis has two additional challenges. For the clustering process, a wide variety of indices have been proposed to find the optimal number of clusters [Charrad et al., 2012] and one of many statistical approaches has to be selected to test for the clustering tendency or so-called clusterability [Adolfsson et al., 2019; Thrun, 2020]. After an extensive review of algorithms of behavior-based systems in unsupervised machine learning, two interesting concepts are addressed here, called self-organization and swarm intelligence. Moreover, two missing links are identified: emergence [Goldstein, 1999; Ultsch, 1999] and game theory [Nash, 1951].

The irreducible structures of high-dimensional data can emerge through self-organization in a phenomenon called emergence. Exploiting the Nash equilibrium concept from game theory [Nash, 1950] through the use of a swarm of intelligent agents, the data-driven approach presented in this work can outperform the optimization of a global objective function in the tasks of clustering. This is demonstrated using a collection of datasets offering a variety of real-world challenges, such as outliers or density vs. distance-defined clusters [Thrun and Ultsch, 2020].

2 Methods

The algorithms of DBS consists of three modules: projection with Pswarm, visualization via a topographic map of projected points and clustering.

2.1 Pswarm

The term planar projection method is often used for one type of dimensionality reduction methods. The output of a projection method is a scatter plot of projected points. Many projection methods are characterized by an objective function that is optimized using gradient descent or a corresponding learning algorithm [Thrun, 2018]. The quality of the projection and, consequently, the visualization will critically depend on the similarity concept chosen as the basis of the objective function [Thrun, 2018].

Focusing projection methods first adapt to global structures, and as time progresses, structure preservation shifts
from global optimization to the preservation of local neighborhoods. Projections of this type (e.g., NerV, CCA, ESOM, t-SNE) usually require parameters to be set because this phase, which is also called the learning phase, requires an annealing scheme. This task is challenging if no prior knowledge about the data exists.

In contrast to all other conventional projection methods, Pswarm neither does have any global objective function nor requires any input parameters other than the data set of interest. In this case, Euclidean distances are used in the input space. Alternatively, a user may also provide Pswarm with a matrix defined in terms of a particular dissimilarity measure, which is typically a distance but may also be a non-metric measure.

The intelligent agents of Pswarm, called DataBots [Ultsch, 2000] operate on a toroid grid, where positions are coded into polar coordinates to allow for the precise definition of their movement, neighborhood function, and annealing scheme. The size of the grid and, in contrast to other focusing projection methods, the annealing scheme are data-driven. During learning, each agent moves across the grid or stays in its current position in the search for the most potent scent emitted by other DataBots. Hence, agents search for other agents carrying data with the most similar features to themselves with a data-driven decreasing search radius. The movement of every agent is modeled using a game-theory approach, and the radius decreases only if a Nash equilibrium is found [Nash, 1950]. After the self-organization of agents is finished, the output of the Pswarm algorithm is a scatter plot of projected points.

2.2 Topographic Map

The goal of this scatter plot is a visualization of distance and density-based structures, which is often used in cluster analysis [Everitt et al., 2001; Hennig, 2015; Mirkin, 2005; Ritter, 2014]. However, it is stated by the Johnson–Lindenstrauss lemma [Dasgupta and Gupta, 2003] that the two-dimensional similarities in the scatter plot cannot coherently represent high-dimensional structures. For example, similar data points can be mapped onto far-separated points, or a pair of closely neighboring positions represents a pair of distant data points.

Therefore, the generalized U-matrix [Thrun, 2018; Ultsch and Thrun, 2017] is exploited on this projection in the second step using emergence through an unsupervised artificial neural network called a simplified (because parameter-free) emergent self-organizing map. The generalized U-matrix generates the visualization of a topographic map with hypersymmetric tints, which can be vividly described as a virtual 3D landscape with a specific color scale chosen with an algorithm defining the contour lines [Thrun et al., 2016]. The topographic map addresses the central problem in clustering, i.e., the correct estimation of the number of clusters. It allows the assessment of the number of clusters [Thrun et al., 2016] by inspecting the 3D landscape. The color scale and contour lines imitate valleys, ridges, and basins: blue colors indicate small distances (sea level), green and brown colors indicate middle distances (low hills), and shades of gray and white indicate vast distances (high mountains covered with snow and ice). Valleys and basins represent clusters, and the watersheds of hills and mountains represent the borders between clusters. In this 3D landscape, the borders of the visualization are cyclically connected with a periodicity defined by two parameters (L,C).

2.3 Clustering

The semi-automated clustering is performed by calculating the shortest paths [Dijkstra, 1959] of the Delaunay graph between all projected points weighted with high-dimensional distances. This is possible because it was shown that the U-matrix is an approximation of the abstract U-matrix [Lötsch and Ultsch, 2014], which is based on Voronoi cells. Voronoi cells define a Delaunay graph where the edges between every projected point are weighted by the high-dimensional distances of the corresponding data points.

The clustering approach itself involves one of two choices. For each choice, a dendrogram can be visualized, which shows the ultrametric portion of the distance used is visualized (c.f. [Murtagh, 2004]). Large changes in fusion levels of the ultrametric portion of the distance indicate the best cut, but the resulting clustering should always be evaluated by the topographic map.

2.4 Open Source Access

There is a general need for open-source implementations in swarm intelligence algorithms [Martens et al., 2011]. Thus, DBS is available as the R package “DatabionicSwarm” on CRAN (https://CRAN.R-project.org/package=DatabionicSwarm). Datasets are available in [Thrun and Ultsch, 2020]. The top 50 clustering algorithms are summarized in the R package “FCPS” on CRAN (https://CRAN.R-project.org/package=FCPS). A small subset of algorithms was selected for benchmarking in this work because for this subset the implicit assumptions were known in literature.

In the following section, the authors provide an exemplary usage of the algorithms based on data of 212 countries about the COVID-19 pandemic. The measured features of the COVID-19 virus and today's data is accessible in the Worldometer's COVID-19 (https://www.worldometers.info/coronavirus/). It should be noted that the data has a high amount of uncertainty because not all countries have the same reporting system or transparency. The source code, data extracted at 16.April 2020, and all analysis steps are accessible in https://zenodo.org/badge/latestdoi/257287298.

3 Exemplary Result of DBS

The following result serves as an illustration of the DBS algorithms. One topographic map is shown in Figure 1. Each point is labeled by a color that defines the cluster in which the point lies in. In this example, each point represents a country.

Figure 2 presents the evaluation of the clustering using a heatmap of distances ordered by the clustering. It is visible that similar countries are in a cluster and more dissimilar countries between clusters. Further, external quality assessment should be performed. Exemplary, it is shown that the clustering is coherent with regards to the spatial distribution of countries per clusters in Figure 3 which was generated using the R package ‘DataVisualizations’ (https://
4 Exemplary Interpretation

The coexistence of high-dimensional structures visualization and clustering allows performing a valid cluster analysis even if the user is not an expert in clustering. DBS is able to find cluster structures for which countries “look like” each other but do not look much like objects outside the cluster (c.f. [Bonner, 1964]) even in this data with a high amount of uncertainty and noise. However, it remains a challenge to evaluate the cluster structures are meaningful. For example, the explanation of the magenta cluster (low death rate with high recovery rate) is questionable as it is more probable that these countries did not provide accurate data.

5 Pitfalls and Advantages in using DBS

Clustering algorithms possess the dilemma that they have to be simultaneously stable but exhibit plasticity allowing for the creation of new cluster structures [Duda et al., 2001].

The benchmarking with conventional algorithms of Ward, single linkage, mixtures of Gaussians, k-means, spectral clustering, and PAM showed this dilemma. Clustering algorithms either have a small variance in results but are unable to produce many cluster structures or have a large variance and a smaller bias w.r.t cluster structures. For other machine learning approaches, this effect is well studied (e.g. [Geman et al., 1992]). This work showed that clustering algorithms impose non-existent cluster structures on the data if their bias is large w.r.t. the data. In contrast, DBS enables the investigation of the cluster tendency and allows the user to improve the clustering if the topographic map is used interactively as shown in the attached source code.

In general, the bias of DBS is small, meaning that many different cluster challenges can be resolved, but the variance of results is sometimes considerable, meaning that in these cases, the result depends on the trial. As shown in the source code on the example above, in praxis, the user has the additional task to cut out an island from the toroidal topographic map (c.f. [Thrun et al., 2016]).

The main pitfall of DBS is its computational complexity because for each row of data (high-dimensional data point), one additional agent (DataBot) has to be initialized, and the available open-source code lacks programming efficiency.

6 Conclusion

By exploiting the missing links between swarm-based algorithms and emergence as well as game theory, the main advantage of DBS is its robustness regarding very different types of distance and density-based structures of clusters. As a technique that uses swarm intelligence, DBS clustering is more robust with respect to outliers than conventional algorithms. DBS enables even a non-professional in the field of data mining to integrate its algorithms for visualization and/or clustering in their knowledge discovery process because no prior knowledge about the data is required, and no implicit
assumptions about the data are made.
