## Abstract

We introduce a new model-based incremental choice procedure for multicriteria decision support, that interleaves the analysis of the set of alternatives and the elicitation of weighting coefficients that specify the role of criteria in rank-dependent models such as ordered weighted averages (OWA) and Choquet integrals. Starting from a prior distribution on the set of weighting parameters, we propose an adaptive elicitation approach based on the minimization of the expected regret to iteratively generate preference queries. The answers of the Decision Maker are used to revise the current distribution until a solution can be recommended with sufficient confidence. We present numerical tests showing the interest of the proposed approach.

## 1 Introduction

Designing efficient preference elicitation methods is one of the major challenges of computer-aided decision support. Various preference models have been proposed and studied in Decision Theory for modeling individual values and generating personalized recommendations. These models use preference parameters that must be tuned to the value system of the Decision Maker (DM). In multicriteria decision support, the key parameters that must be elicited to perform the preference aggregation are weighting coefficients that specify the role of criteria in the aggregation, in particular their relative importance and sometimes also their level of interaction, see e.g., [Tehrani *et al.*, 2012]. Weighting coefficients can be elicited in a preliminary step and used for several recommendation tasks or can alternatively be elicited on the fly during the exploration of the set of alternatives. The latter approach, said to be *incremental*, has been widely investigated in AI in order to reduce the elicitation burden. Several utility elicitation methods are now available, see e.g., [Ha and Haddawy, 1997; Chajewska *et al.*, 2000; Blythe, 2002; Wang and Boutilier, 2003; Braziliunas and Boutilier, 2007]. The incremental approach makes it possible to concentrate the elicitation effort on the part of the preferential information that is sufficient to determine an optimal choice. It also makes it possible to adapt the questionnaire to DM's answers, to quickly dispel the uncertainty attached to incomparable alternatives.

One key aspect of interactive preference elicitation is to limit the number of preference queries without downgrading the quality of recommendations. To this end, efficient adaptive elicitation strategies have been proposed allowing a fast reduction of the space of possible parameters until it becomes sufficiently small to be able to determine the optimal choice without ambiguity. For example, this is the case of incremental elicitation methods based on the minimization of the maximum regret proposed in [Wang and Boutilier, 2003; Boutilier *et al.*, 2006; Benabbou and Perny, 2015; Benabbou *et al.*, 2017]. Preference queries are generated to reduce the imprecision of parameters and the regrets attached to the possible decisions. The responses are translated into hard constraints limiting the space of admissible parameters and allowing sharper preferences to be derived. No opportunity is nevertheless given to the DM to contradict herself. In these approaches relying on a progressive and backtrack-free reduction of the uncertainty set, the efficiency comes at the cost of a relative lack of robustness in recommendation tasks, as illustrated by the following example.

**Example 1** *We consider a set  $\mathcal{A}$  of alternatives in a bi-criteria decision problem containing 101 elements characterized by their performance vectors  $\mathbf{a}^i = (i, 100 - i)$ ,  $i = 0, \dots, 100$ . We assume here that the DM's preferences can be represented by an ordered weighted average (OWA) of the form:  $u_w(\mathbf{a}^i) = w \min\{a_1^i, a_2^i\} + (1 - w) \max\{a_1^i, a_2^i\}$  with  $w = 0.6$ . Hence,  $u_{0.6}(\mathbf{a}^i) = 40 + 0.2i$ ,  $\forall i \in \llbracket 0, 50 \rrbracket$  and  $u_{0.6}(\mathbf{a}^i) = 60 - 0.2i$ ,  $\forall i \in \llbracket 51, 100 \rrbracket$  and the  $u_{0.6}$ -optimal solution is  $\mathbf{a}^{50} = (50, 50)$  with utility 50. We remark here the interest of OWA aggregation that selects the better balanced vector in  $\mathcal{A}$ . Such a selection could not be performed with a linear model. Assume now that  $w$  is unknown and must be elicited. Hence the set of possible values for  $w$  is  $W = [0, 1]$ . Assume that the DM first declares that  $\mathbf{a}^k$  is at least as good as  $\mathbf{a}^i$  for some  $i < k \leq 50$ . From  $u_w(\mathbf{a}^k) \geq u_w(\mathbf{a}^i)$  we obtain  $w \geq 0.5$  and therefore  $W = [1/2, 1]$ . After this reduction, the optimal solution in  $\mathcal{A}$  is necessarily  $\mathbf{a}^{50}$ . We indeed have  $u_w(\mathbf{a}^{50}) - u_w(\mathbf{a}^k) = (50 - k)(2w - 1) \geq 0$  for all  $k \in \llbracket 0, 50 \rrbracket$  and  $w \in [1/2, 1]$ , and  $u_w(\mathbf{a}^{50}) - u_w(\mathbf{a}^k) = 50 - 100w + i \geq 0$  for all  $k \in \llbracket 51, 100 \rrbracket$  and  $w \in [1/2, 1]$ . If the DM answers that  $\mathbf{a}^i$  is strictly better than  $\mathbf{a}^k$  for some  $i < k \leq 50$ , a similar treatment would lead to conclude that  $W = [0, 1/2]$  and that  $\mathbf{a}^0$  and  $\mathbf{a}^{100}$  are necessarily optimal in  $\mathcal{A}$ . In both cases, an optimum is found after one preference query.*

This example shows the efficiency of incremental preference elicitation in a simple case of bi-criteria decision making using an OWA. The optimal choice can be determined while the uncertainty about criteria weights remains very large. This example also illustrates the high sensitivity of the method to possible errors made by the DM in expressing her preferences. If the DM unfortunately declares that she strictly prefers  $\mathbf{a}^i$  to  $\mathbf{a}^k$  for some  $i < k \leq 50$  while its utility function is  $u_{0.6}$ , we may recommend  $\mathbf{a}^0$  which is actually the worst option. This lack of robustness is due to definitive reductions of the uncertainty set  $W$  resulting from hard constraints derived from the observed preferences at every step. In case of a wrong answer, the uncertainty set will definitely exclude the correct value of the hidden parameters and reduce the relevance of recommendations. In this paper we keep unchanged the uncertainty set, and maintain a probability density function over it. The distribution is updated in a Bayesian manner.

## 2 Preliminaries

### 2.1 Rank-dependent Aggregation Functions

Let  $\mathcal{A}$  be the set of alternatives that need to be compared in order to make a decision. Any alternative  $a \in \mathcal{A}$  is evaluated with respect to a set of  $p$  criteria denoted by  $C = \{1, \dots, p\}$ , and is characterized by a performance vector  $\mathbf{a} = (a_1, \dots, a_p)$ , where  $a_i \in [0, 1]$  represents the utility of  $a$  with respect to criterion  $i$ . All utilities  $a_i$  are expressed on the same scale; the utility functions must be defined from the input data (criterion or attribute values), as proposed by, e.g., Grabisch and Labreuche [2010]. From now on, for simplicity, we will consider the image of  $\mathcal{A}$  in the criteria space, denoted by abuse of notation  $\mathcal{A} = \{\mathbf{a}^1, \dots, \mathbf{a}^n\}$ , and indifferently use the terms ‘‘alternative’’ and ‘‘performance vector’’.

A standard way to model preferences between performance vectors consists in using an aggregation function that maps vectors to scalar values. The function is called *rank-dependent* if the vector is sorted in nondecreasing order before being mapped into a scalar value. This enables to assign weighting coefficients to components of the performance vector according to their ranks. Given a vector  $\mathbf{a}$ , we denote by  $(\cdot)$  a permutation on  $C$  such that  $a_{(1)} \leq \dots \leq a_{(p)}$ .

We will consider two families of rank-dependent aggregation functions, namely *ordered weighted averages* (OWA) and *Choquet integrals*. These aggregation functions are known to be monotonic with respect to weak Pareto dominance ( $\mathbf{a}$  weakly dominates  $\mathbf{b}$  if  $a_i \geq b_i$  for  $i \in \{1, \dots, p\}$ ).

#### Ordered Weighted Averages

This family of aggregation functions has been introduced by Yager (1988). Let  $\boldsymbol{\lambda} = (\lambda_1, \dots, \lambda_p)$  be a weighting vector ( $\sum_{i=1}^p \lambda_i = 1$  and  $\lambda_i \geq 0 \forall i$ ). The OWA defined by  $\boldsymbol{\lambda}$  reads:

$$\text{OWA}_{\boldsymbol{\lambda}}(\mathbf{a}) = \sum_{i=1}^p \lambda_i a_{(i)}. \quad (1)$$

Note that the OWA aggregator includes the min, the max and the arithmetic mean as special cases. The OWA function is concave if  $\lambda_1 \geq \dots \geq \lambda_p$ . The subclass of concave OWA functions is of particular interest in fair optimization because  $\text{OWA}((a_1, \dots, a_i - \varepsilon, \dots, a_j + \varepsilon, \dots, a_p)) \geq \text{OWA}(\mathbf{a})$  for all  $i, j, \varepsilon$  such that  $a_i - a_j \geq \varepsilon > 0$ . It thus favors well-balanced performances. While instances of OWA range from the min

( $\lambda_1 = 1$  and  $\lambda_i = 0 \forall i > 0$ ) to the max ( $\lambda_p = 1$  and  $\lambda_i = 0 \forall i < p$ ) depending on the weights, instances of *concave* OWA range from the min to the arithmetic mean ( $\lambda_i = 1/p \forall i$ ).

**Example 2** Let  $\mathbf{a} = (0.3, 0.5, 0.8)$  and  $\mathbf{b} = (0.5, 0.6, 0.4)$ . For  $\boldsymbol{\lambda} = (0.5, 0.3, 0.2)$ , we have  $\text{OWA}_{\boldsymbol{\lambda}}(\mathbf{a}) = 0.46 < 0.47 = \text{OWA}_{\boldsymbol{\lambda}}(\mathbf{b})$ , thus  $\mathbf{b}$  is preferred to  $\mathbf{a}$ .

#### Choquet Integrals

The Choquet integral [Schmeidler, 1986; Grabisch *et al.*, 2009] is an aggregation function that generalizes the notion of average, by defining a *capacity* on the criteria set. A capacity is a set function from  $2^C$  to  $\mathbb{R}$  such that  $v(\emptyset) = 0$ ,  $v(C) = 1$  and  $v(X) \leq v(Y)$  for all  $X \subseteq Y \subseteq C$ . In multicriteria analysis,  $v(X)$  represents the weight attached to coalition  $X$ , for any  $X \subseteq C$ . The Choquet integral defined by  $v$  reads:

$$C_v(\mathbf{a}) = \sum_{i=1}^p (v(A_{(i)}) - v(A_{(i+1)})) a_{(i)} \quad (2)$$

$$= \sum_{i=1}^p [a_{(i)} - a_{(i-1)}] v(A_{(i)}) \quad (3)$$

where  $A_{(i)} = \{(i), \dots, (p)\}$  (i.e., the criteria whose performance is greater or equal to  $a_{(i)}$ ),  $v(A_{(p+1)}) = 0$  and  $a_{(0)} = 0$ . Note that the Choquet integral includes the weighted sum as a special case: if  $v$  is additive, i.e.,  $v(X) = \sum_{i \in X} \lambda_i$  for some positive coefficients  $\lambda_i$ , then Equation 2 leads to  $C_v(\mathbf{a}) = \sum_i \lambda_i a_i$ . The Choquet integral also includes the OWA function as special case. Indeed, if we use a *symmetric* capacity  $v$  in Equation 2, i.e.,  $v(X)$  only depends on  $|X|$ , then  $\lambda_i = v(A_{(i)}) - v(A_{(i+1)})$  only depends on  $i$  and not on the elements in  $A_{(i)}$  and  $A_{(i+1)}$ , thus we recognize an OWA.

**Example 3** Let us come back to Example 2. Consider the capacity  $v$  defined by  $v(\emptyset) = 0$ ,  $v(C) = 1$  and:

$X$	{1}	{2}	{3}	{1, 2}	{1, 3}	{2, 3}
$v(X)$	0.1	0.2	0.3	0.5	0.5	0.6

The evaluations of  $\mathbf{a}$  and  $\mathbf{b}$  using Equation 3 are:

$$C_v(\mathbf{a}) = 0.3 v(C) + 0.2 v(\{2, 3\}) + 0.3 v(\{3\}) = 0.51$$

$$C_v(\mathbf{b}) = 0.4 v(C) + 0.1 v(\{1, 2\}) + 0.1 v(\{2\}) = 0.47$$

Thus  $C_v(\mathbf{a}) > C_v(\mathbf{b})$  and  $\mathbf{a}$  is preferred to  $\mathbf{b}$ .

We now recall a useful representation of capacities in terms of *Möbius inverse*. The Möbius inverse of a capacity  $v$  is a mapping  $m_v : 2^C \rightarrow \mathbb{R}$  defined by  $m_v(X) = \sum_{Y \subseteq X} (-1)^{|X \setminus Y|} v(Y) \forall X \subseteq C$ . The quantity  $m_v(X)$  is called the *Möbius mass* of  $X$ . The capacity can be derived from its Möbius inverse as follows:  $\forall X \subseteq C$ ,  $v(X) = \sum_{Y \subseteq X} m_v(Y)$ . The Möbius inverse yields an alternative formulation of the Choquet integral:

$$C_v(\mathbf{a}) = \sum_{X \subseteq C} m_v(X) \min_{i \in X} a_i$$

A capacity  $v$  is said to be *k-additive* if  $m_v(X) = 0$  for all  $X \subseteq C$  such that  $|X| > k$  and there exists at least one subset  $X$  such that  $|X| = k$  and  $m_v(X) > 0$ . For instance, the capacity  $v$  considered in Example 3 is at most 2-additive because:  $m(\{1, 2, 3\}) = v(\{1, 2, 3\}) - \sum_{i \neq j} v(\{i, j\}) + \sum_i v(\{i\}) = 0$ . The main interest of Choquet integrals for multicriteria decision making stems from the fact that they can represent interaction between criteria [Grabisch and Labreuche, 2010], as can be witnessed by the Möbius masses. For instance, by definition,  $m_v(\{i, j\}) = v(\{i, j\}) - v(\{i\}) - v(\{j\})$ . There is a positive interaction between  $i$  and  $j$  if  $m_v(\{i, j\}) > 0$ ,

and negative if  $m_v(\{i, j\}) < 0$ . The  $k$ -additive capacities for small values of  $k$  greater than 1 are very useful because in practical situations, they offer a sufficient expressivity to model positive or negative synergies between criteria with a reduced number of parameters. For example, when  $k = 2$  the capacity is completely characterized by  $(p^2 + p)/2$  coefficients (one Möbius mass for every singleton and every pair).

The aggregation functions introduced above are intended to be used to describe the preferences of the DM, thus their parameters (i.e., the weighting vector or the capacity) must be inferred from preference statements provided by the DM.

## 2.2 Related Works

Regarding the Bayesian incremental elicitation of an aggregation function from pairwise preference queries, the previous works in the literature can be divided in two categories: non-parametric approaches and parametric approaches.

Following a *nonparametric approach*, Chu and Ghahramani [2005] proposed to use Gaussian Processes (GP) for preference learning. To approximate *any* possible aggregation function, the idea is to assume that each overall utility value follows a normal distribution. The joint distribution defines a GP. This distribution is characterized by a mean function and a covariance matrix, and can be seen as an infinite-dimensional extension of a multivariate Gaussian distribution (the domain of the aggregation function can indeed be infinite). The covariance matrix is used to ensure that alternatives with similar performance vectors yield similar overall utility values. Building on this work, Brochu *et al.* [2007] proposed an active learning procedure that does not require to accurately model the entire aggregation function to determine an optimal alternative. Their approach is based on pairwise comparison queries. Zintgraf *et al.* [2018] recently extended it to other query types, like asking the user to rank or cluster alternatives. In this paper, we investigate a parametric approach where one imposes a rank-dependent aggregation function to ensure appealing normative properties.

A *parametric approach* consists indeed in learning the parameters of a given aggregation function. This kind of approaches was well introduced and illustrated in [Chajewska *et al.*, 2000] for the adaptive elicitation of utility values over a finite set of outcomes in decision making under uncertainty. While their approach used standard gamble queries (pairwise preference queries between probability distributions over outcomes), Guo and Sanner [2010] proposed a variant that only requires the users to state their preference under certainty, so as to reduce the cognitive load. Recently, for the adaptive elicitation of the parameters of a multiattribute utility function, Sauré and Vielma [2018] proposed an approach that updates an ellipsoidal credibility region computed from a multivariate normal distribution over the space of parameters, and showed how to use mixed integer programming to determine queries that are likely to reduce the volume of the credibility region. Nonetheless, none of these works is concerned with learning the parameters of a *rank-dependent* aggregation function, which is the aim of the present paper.

Most of the works aiming at determining the parameters of rank-dependent aggregation functions consider a static preference database as input, and focus on the determination of

parameter values that best fit the available preferences. For learning the parameters of a Choquet integral, Marichal and Roubens [2000] presented a linear programming formulation, Tehrani *et al.* [2012] proposed a generalization of logistic regression, and Rowley *et al.* [2015] used a principal component analysis. Departing from these works, incremental elicitation procedures have recently been proposed [Benabbou *et al.*, 2017; Bourdache and Perny, 2019], but they assume no response-error. Yet, as illustrated in Example 1, the recommendation made can be severely impacted by errors in responses. To overcome this drawback, we introduce in the next section some useful linear and compact reformulations of OWA and Choquet aggregators in new multidimensional spaces, that makes it possible to implement Bayesian linear regression techniques with rank-dependent models.

## 3 Basis Functions for OWA and Choquet

A way to extend Bayesian linear regression to a nonlinear function  $f$  is to reformulate  $f$  as a linear combination of (non-linear) *basis functions*  $g_1, \dots, g_q$  [Bishop, 2006]. Formally:

$$f(\mathbf{a}) = \sum_{i=1}^q w_i g_i(\mathbf{a}) = \mathbf{w}^T \mathbf{g}(\mathbf{a})$$

where  $\mathbf{w} = (w_1, \dots, w_q)^T$  is a weighting vector and  $\mathbf{g}(\mathbf{a}) = (g_1(\mathbf{a}), \dots, g_q(\mathbf{a}))^T$ . Thus,  $f$  is a linear function in the space of features  $g_1, \dots, g_q$ . We now introduce suitable basis functions for the rank-dependent aggregators studied here.

### Ordered Weighted Averages

Obviously, any OWA function is a linear combination of functions  $g_i(\mathbf{a}) = a_{(i)}$  for  $i = 1, \dots, p$  (see Equation 1). Given a weighting vector  $\lambda$  for OWA, the corresponding parameters for the basis functions are  $w_i = \lambda_i$  for  $i = 1, \dots, p$ . For the OWA function to be nondecreasing in every component, we impose  $w_i \geq 0$  for  $i = 1, \dots, p$ .

### Concave Ordered Weighted Averages

In the context of fair optimization, the constraint  $w_1 \geq \dots \geq w_p$  is required to favor solutions having balanced profile [Weymark, 1981], which makes the linearization more tricky. In this case we get a concave OWA function. To overcome the problem, we shall use cumulative functions defined by  $g_i(\mathbf{a}) = \sum_{k=1}^i a_{(k)}$ . It can easily be checked that:

$$\text{OWA}_\lambda(\mathbf{a}) = \sum_{i=1}^p w_i \left( \sum_{k=1}^i a_{(k)} \right)$$

where  $w_i = \lambda_i - \lambda_{i+1}$  for  $i < p$  and  $w_p = \lambda_p$ . Conversely, given parameters  $w_k$ , the corresponding weights for OWA are  $\lambda_i = \sum_{k=i}^p w_k$ . Note that to enforce constraint  $\lambda_1 \geq \dots \geq \lambda_p \geq 0$ , we only have to impose  $w_i \geq 0$  for  $i = 1, \dots, p$ .

**Example 4** For  $\lambda = (0.5, 0.3, 0.2)$  (as in Example 2), the expression  $\text{OWA}_\lambda(\mathbf{a})$  reformulates as  $0.2g_1(\mathbf{a}) + 0.1g_2(\mathbf{a}) + 0.2g_3(\mathbf{a})$ . If  $\mathbf{a} = (0.3, 0.5, 0.8)$ , we have  $\mathbf{g}(\mathbf{a}) = (0.3, 0.8, 1.6)$  and  $\text{OWA}_\lambda(\mathbf{a}) = 0.2 \times 0.3 + 0.1 \times 0.8 + 0.2 \times 1.6 = 0.46$ .

### 2-additive Choquet Integrals

To express a Choquet integral as a linear combination of basis functions, we consider a decomposition of  $v$  under the form  $v = \sum_{i=1}^q w_i v_i$ , where  $v_i$ 's are basis capacity functions. Indeed, if  $v = \sum_{i=1}^q w_i v_i$ , then  $C_v(\mathbf{a}) = \sum_{i=1}^q w_i C_{v_i}(\mathbf{a})$  because  $C_v$  is linear in  $v$ . For the class of at most 2-additive capacities,

a decomposition of  $v$  with  $q = p^2$  basis functions is known. This class can be characterized by a polytope, the extreme points of which are defined by two families of 0-1 capacities:

- the *unanimity games* for singletons and pairs defined by

$$v_i(X) = \begin{cases} 1 & \text{if } Y_i \subseteq X \\ 0 & \text{otherwise} \end{cases} \quad \text{for } i \in \llbracket 1, \frac{p(p+1)}{2} \rrbracket$$

where  $Y_i \subseteq C$  is any nonempty subset of size at most 2;

- the *conjugates* of unanimity games for pairs defined by

$$v_i(X) = \begin{cases} 1 & \text{if } Y_i \cap X \neq \emptyset \\ 0 & \text{otherwise} \end{cases} \quad \text{for } i \in \llbracket \frac{p(p+1)}{2} + 1, p^2 \rrbracket$$

where  $Y_i \subseteq C$  is any subset of size 2.

This characterization of extreme points directly follows from [Grabisch, 2016, Theorem 2.65, p.89]. Hence, for any at most 2-additive capacity, there exists  $p^2$  coefficients  $w_i \geq 0$  adding up to 1 such that  $C_v(\mathbf{a}) = \sum_i w_i C_{v_i}(\mathbf{a})$ . Note that a similar result, formulated in terms of Möbius inverse, has also been used in [Hüllermeier and Tehrani, 2013].

**Example 5** Any capacity  $v$  on three criteria can be written as a convex combination of  $v_i$ 's in the table below (the unanimity games are  $v_1, \dots, v_6$ , the conjugates are  $v_7, v_8, v_9$ ).

$X$	{1}	{2}	{3}	{1,2}	{1,3}	{2,3}
$v_1(X)$	1	0	0	1	1	0
$v_2(X)$	0	1	0	1	0	1
$v_3(X)$	0	0	1	0	1	1
$v_4(X)$	0	0	0	1	0	0
$v_5(X)$	0	0	0	0	1	0
$v_6(X)$	0	0	0	0	0	1
$v_7(X)$	1	1	0	1	1	1
$v_8(X)$	1	0	1	1	1	1
$v_9(X)$	0	1	1	1	1	1

For  $\mathbf{a} = (0.3, 0.5, 0.8)$ , we have  $C_{v_1}(\mathbf{a}) = 0.3$ ,  $C_{v_2}(\mathbf{a}) = 0.5$ ,  $C_{v_3}(\mathbf{a}) = 0.8$ ,  $C_{v_4}(\mathbf{a}) = 0.3$ ,  $C_{v_5}(\mathbf{a}) = 0.3$ ,  $C_{v_6}(\mathbf{a}) = 0.5$ ,  $C_{v_7}(\mathbf{a}) = 0.5$ ,  $C_{v_8}(\mathbf{a}) = 0.8$ ,  $C_{v_9}(\mathbf{a}) = 0.8$ . Besides,  $v = 0.1v_2 + 0.3v_3 + 0.3v_4 + 0.1v_5 + 0.1v_6 + 0.1v_7$ , thus  $C_v(\mathbf{a}) = 0.51$ .

## 4 Incremental Elicitation Process

We now introduce an incremental Bayesian elicitation procedure taking advantage of the above linear reformulations. We consider a non-linear aggregation function admitting a linear representation  $f_{\mathbf{w}}(\mathbf{a}) = \mathbf{w}^T \mathbf{g}(\mathbf{a})$ , where values  $g_i(\mathbf{a})$  are computed as shown in Section 3. Incremental decision making consists in implementing an adaptive elicitation procedure based on  $f_{\mathbf{w}}$  to iteratively collect preference statements so as to reduce the uncertainty about  $\mathbf{w}$  until an alternative can be recommended with sufficient confidence. We propose a Bayesian approach where a prior density function over the parameter space is iteratively updated with new preference statements. The incremental decision process is based on the progressive minimization of expected regrets attached to possible decisions. The expected regrets are defined as follows.

**Definition 1** Given a density function  $p$  on the possible values of  $\mathbf{w}$ , the pairwise expected regret of an alternative  $\mathbf{a}$  with respect to an alternative  $\mathbf{b}$  is defined as follows:

$$\text{PER}(\mathbf{a}, \mathbf{b}, p) = \int \max\{0, f_{\mathbf{w}}(\mathbf{b}) - f_{\mathbf{w}}(\mathbf{a})\} p(\mathbf{w}) d\mathbf{w}$$

In other words, the pairwise expected regret of  $\mathbf{a}$  with respect to  $\mathbf{b}$  represents the expected utility loss when recommending  $\mathbf{a}$  instead of  $\mathbf{b}$ .

**Definition 2** Given a set  $\mathcal{A}$  of alternatives and a density function  $p$  on the possible values of  $\mathbf{w}$ , the max expected regret of  $\mathbf{a} \in \mathcal{A}$  and the minimax expected regret are defined by:

$$\text{MER}(\mathbf{a}, \mathcal{A}, p) = \max_{\mathbf{b} \in \mathcal{A}} \text{PER}(\mathbf{a}, \mathbf{b}, p)$$

$$\text{MMER}(\mathcal{A}, p) = \min_{\mathbf{a} \in \mathcal{A}} \text{MER}(\mathbf{a}, \mathcal{A}, p)$$

In other words, the max expected regret<sup>1</sup> of  $\mathbf{a}$  is the maximum expected utility loss incurred in selecting  $\mathbf{a}$  in  $\mathcal{A}$ .

### Incremental Elicitation

We denote by  $\mathbf{a}^{(k)}$  an alternative achieving the  $\text{MMER}(\mathcal{A}, p)$  value at iteration  $k$ . This alternative is worth recommending if no further preferential information can be obtained because it minimizes the expected opportunity loss. Otherwise, we ask the DM to compare  $\mathbf{a}^{(k)}$  and any adversarial choice  $\mathbf{b}^{(k)}$  in  $\arg \max_{\mathbf{b} \in \mathcal{A}} \text{PER}(\mathbf{a}^{(k)}, \mathbf{b}, p)$ , as suggested by Boutilier *et al.* (2006) in the context of max regret minimization (*current solution strategy*). The DM's answer allows us to update the current distribution  $p$  for the next iteration. This process can be iterated until the MMER value drops below a given acceptance threshold  $\delta$ . The resulting incremental decision procedure is more formally described in Algorithm 1.

---

#### Algorithm 1 Incremental decision making

---

**Input:**  $\mathcal{A}$ : alternatives;  $\delta$ : threshold;  $p(\mathbf{w})$ : density function.

**Output:**  $\mathbf{a}^*$ : best recommendation in  $\mathcal{A}$ .

```

1  $i \leftarrow 1$ ;
2 repeat
3    $\mathbf{a}^{(i)} \leftarrow \arg \min_{\mathbf{a} \in \mathcal{A}} \text{MER}(\mathbf{a}, \mathcal{A}, p)$ 
4    $\mathbf{b}^{(i)} \leftarrow \arg \max_{\mathbf{b} \in \mathcal{A}} \text{PER}(\mathbf{a}^{(i)}, \mathbf{b}, p)$ 
5   Ask the DM if  $\mathbf{a}^{(i)}$  is preferred to  $\mathbf{b}^{(i)}$ 
6    $y^{(i)} \leftarrow 1$  if the answer is yes and 0 otherwise
7    $p(\mathbf{w}) \leftarrow p(\mathbf{w}|y^{(i)}) \quad \forall \mathbf{w}$  (see Algorithm 2)
8    $i \leftarrow i + 1$ 
9 until  $\text{MMER}(\mathcal{A}, p) \leq \delta$ 
10 return  $\mathbf{a}^*$  selected in  $\arg \min_{\mathbf{a} \in \mathcal{A}} \text{MER}(\mathbf{a}, \mathcal{A}, p)$

### Bayesian Inference

In Line 7, the density function  $p(\mathbf{w})$  is updated using the latent variable approach introduced by Albert and Chib (1993) for binary *probit* regression. Let  $y^{(i)}$  represent the answer to a comparison query  $i$  between  $\mathbf{a}^{(i)}$  and  $\mathbf{b}^{(i)}$ , with  $y^{(i)} = 1$  if  $\mathbf{a}^{(i)}$  is preferred,  $y^{(i)} = 0$  otherwise. In our setting, the probit model is used to predict the value of  $y^{(i)}$  based on the vector  $\mathbf{d}^{(i)} = \mathbf{g}(\mathbf{a}^{(i)}) - \mathbf{g}(\mathbf{b}^{(i)})$  of explanatory variables. The answer  $y^{(i)}$  is assumed to depend on a latent variable  $z^{(i)}$  representing preference intensity and defined by:

$$z^{(i)} = \mathbf{w}^T \mathbf{d}^{(i)} + \varepsilon^{(i)} \quad (4)$$

where  $\varepsilon^{(i)} \sim \mathcal{N}(0, 1)$  is a Gaussian noise accounting for possible errors in the answers and for descriptive limitations of the preference model. If  $z^{(i)} \geq 0$ , then  $y^{(i)} = 1$ , else  $y^{(i)} = 0$ .

Following the sequential Bayesian approach of Algorithm 1, a prior density function  $p(\mathbf{w})$  is defined on the parameter space. In the probit model,  $p(\mathbf{w})$  is multivariate Gaussian. After each query, the current density function  $p(\mathbf{w})$

<sup>1</sup>Note that there exists similar definitions of expected regrets in the literature (see, e.g., Guo and Sanner [2010]).

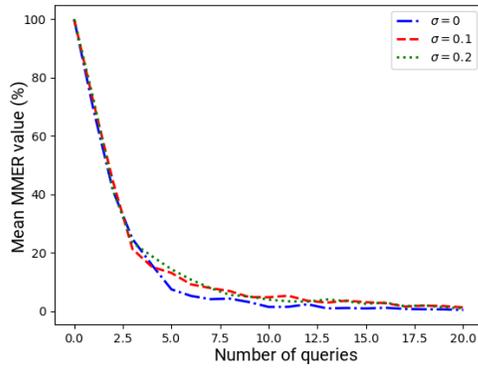

Figure 1: Mean MMER value (OWA)

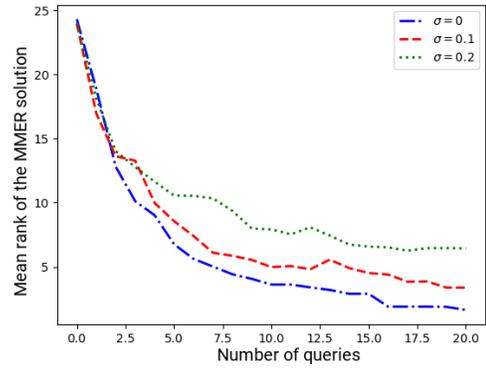

Figure 2: Mean rank of the recommendation (OWA)

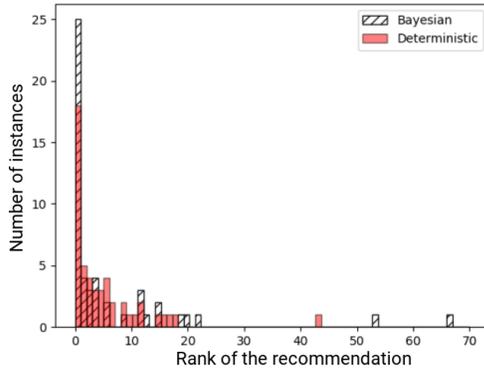

Figure 3: Rank of the recommendation (OWA)

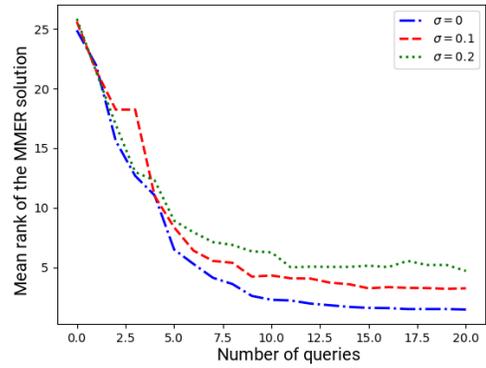

Figure 4: Mean rank of the recommendation (Choquet)

## Analysis of the Results

We evaluated the efficiency of Algorithm 1 with respect to the value of  $\sigma$  (results averaged over 50 instances).

We first observed the evolution of the MMER value in the course of Algorithm 1, in percentage of the initial MMER value (the curves for OWA and 2-additive Choquet are very similar, thus only the former are provided), as well as the evolution of the actual rank in  $\mathcal{A}$  of the current MMER alternative according to the hidden DM preference model. The obtained curves for OWA and at most 2-additive Choquet integrals are represented in Figure 1, 2 and 4. We observe that the mean MMER value drops below 3% of the initial MMER value in a dozen queries. The value of  $\sigma$  mainly impacts the quality of the recommendation, measured by the rank of the recommended alternative in the hidden ranking of the DM, that deteriorates when the value of  $\sigma$  increases. Nevertheless, the average rank of the recommended alternative is never beyond 5 (over 100 alternatives), except for OWA with  $\sigma = 0.2$  where it is around 6.5. Regarding the computation times between two queries, it takes about 5 seconds for OWA, and about 35 seconds for 2-additive Choquet. This difference can be explained by the respective sizes of parameter spaces.

We next compared the performance of Algorithm 1 to a deterministic approach based on the minimization of the max regret, that reduces the parameter space after each query instead of updating a probability density function (see e.g., [Bourdache and Perny, 2019]). For both methods, we considered two performance criteria: the number of queries for making a recommendation, and the quality of the recommendation it-

self, measured in terms of actual rank of the recommended solution at termination. Regarding the number of queries, as can be seen in Figure 2 and 4, the quality of the recommendation does not significantly improve after a dozen query, which is similar to the number of queries in the deterministic approach. Regarding the quality of the recommendation, the histogram in Figure 3 shows the distribution of the ranks of the recommendations over the 50 randomly generated instances, for OWA with  $\sigma = 0.2$ . The Bayesian approach recommends the best alternative in 50% of cases while it happens in 36% of cases for the deterministic approach.

## 6 Conclusion

Our work differentiates from previous works on incremental decision making with OWA and Choquet integrals in proposing a probabilistic approach that is tolerant to response-errors of the DM. It also differentiates from previous work on active preference learning with Bayesian methods in implementing an approach that applies to well-known rank-dependent decision criteria. Our contribution on the Choquet integral concerns the case of 2-additive capacities, that are known to provide sufficient flexibility to model very diverse preference systems including positive and negative interactions between criteria. However, it would be interesting to extend our approach to elicit larger classes of capacities to make even better use of the descriptive possibilities offered by the Choquet integral. This is a challenging problem because the polytope of at most  $k$ -additive capacities for  $k > 2$  admits many other extreme points than 0-1 capacities [Miranda *et al.*, 2006].
