Abstract
Accurate forecasting of extreme values in time series is critical due to the significant impact of extreme events on human and natural systems. This paper presents DeepExtrema, a novel framework that combines a deep neural network (DNN) with generalized extreme value (GEV) distribution to forecast the block maximum value of a time series. Implementing such a network is a challenge as the framework must preserve the inter-dependent constraints among the GEV model parameters even when the DNN is initialized. We describe our approach to address this challenge and present an architecture that enables both conditional mean and quantile prediction of the block maxima. The extensive experiments performed on both real-world and synthetic data demonstrated the superiority of DeepExtrema compared to other baseline methods.

1 Introduction
Extreme events such as droughts, floods, and severe storms occur when the values of the corresponding geophysical variables (such as temperature, precipitation, or wind speed) reach their highest or lowest point during a period or surpass a threshold value. Extreme events have far-reaching consequences for both humans and the environment. For example, four of the most expensive hurricane disasters in the United States since 2005—Katrina, Sandy, Harvey, and Irma—have each incurred over $50 billion in damages with enormous death tolls [US GAO, 2020]. Accurate forecasting of the extreme events [Wang and Tan, 2021] is therefore crucial as it not only helps provide timely warnings to the public but also enables emergency managers and responders to better assess the risk of potential hazards caused by future extreme events.

Despite its importance, forecasting time series with extremes can be tricky as the extreme values may have been ignored as outliers during training to improve the generalization performance of the model. Furthermore, as current approaches are mostly designed to minimize the mean-square prediction error, their fitted models focus on predicting the conditional expectation of the target variable rather than its extreme values [Bishop, 2006]. Extreme value theory (EVT) offers a statistically well-grounded approach to derive the limiting distribution governing a sequence of extreme values [Coles et al., 2001]. The two most popular distributions studied in EVT are the generalized extreme value (GEV) and generalized Pareto (GP) distributions. Given a prediction window, GEV governs the distribution of its block maxima, whereas GP is concerned with the distribution of excess values over a certain threshold, as shown Figure 1. This paper focuses on forecasting the block maxima as it allows us to assess the worst-case scenario in the given forecast time window and avoids making ad-hoc decisions regarding the choice of excess threshold to use for the GP distribution. Unfortunately, classical EVT has limited capacity in terms of modeling highly complex, nonlinear relationships present in time series data. For example, [Kharin and Zwiers, 2005] uses a simple linear model to infer the GEV parameters.

Deep learning methods have grown in popularity in recent years due to their ability to capture nonlinear dependencies in the data. Previous studies have utilized a variety of deep neural network architectures for time series modeling, including long short-term memory networks [Sagheer and Kotb, 2019; Masum et al., 2018; Laptev et al., 2017], convolutional neural networks [Bai et al., 2018; Zhao et al., 2017; Yang et al., 2015], encoder-decoder based RNN [Peng et al., 2018], and attention-based models [Zhang et al., 2019; Aliabadi et al., 2020]. However, these works are mostly focused on predicting the conditional mean of the target variable. While there have some recent attempts to incorporate EVT into deep learning [Wilson et al., 2022; Ding et al., 2019; Polson and Sokolov, 2020], they are primarily focused on modeling the tail distribution, i.e., excess values over a threshold, using the GP distribution, rather than forecasting the block maxima using the GEV distribution. Furthermore, instead of inferring the distribution parameters from data,
some methods [Ding et al., 2019] assume that the parameters are fixed at all times and can be provided as user-specified hyperparameters while others [Polson and Sokolov, 2020] do not enforce the necessary constraints on parameters of the extreme value distribution.

Incorporating the GEV distribution into the deep learning formulation presents many technical challenges. First, the GEV parameters must satisfy certain positivity constraints to ensure that the predicted distribution has a finite bound [Coles et al., 2001]. Maintaining these constraints throughout the training process is a challenge since the model parameters depend on the observed predictor values in a mini-batch. Another challenge is the scarcity of data since there is only one block maximum value per time window. This makes it hard to accurately infer the GEV parameters for each window from a set of predictors. Finally, the training process is highly sensitive to model initialization. For example, the random initialization of a deep neural network (DNN) can easily violate certain regularity conditions of the GEV parameters estimated using maximum likelihood (ML) estimation. An improper initialization may lead to estimates that defy the regularity conditions. For example, if \(\xi < -0.5\), then resulting ML estimators may not have the standard asymptotic properties [Smith, 1985], whereas if \(\xi > 1\), then the conditional mean is not well-defined. Without proper initialization, the DNN will struggle to converge to a feasible solution with acceptable values of the GEV parameters. Thus, controlling the initial estimate of the parameters is difficult but necessary.

To overcome these challenges, we propose a novel framework called DeepExtrema that utilizes the GEV distribution to characterize the distribution of block maximum values for a given forecast time window. The parameters of the GEV distribution are estimated using a DNN, which is trained to capture the nonlinear dependencies in the time series data. This is a major departure from previous work by [Ding et al., 2019], where the distribution parameters are assumed to be fixed, user-specified hyperparameter. DeepExtrema reparameterizes the GEV formulation to ensure that the DNN output is compliant with the GEV positivity constraints. In addition, DeepExtrema offers a novel, model bias offset mechanism in order to ensure that the regularity conditions of the GEV parameters are satisfied from the beginning.

In summary, the main contributions of the paper are:

1. We present a novel framework to predict the block maxima of a given time window by incorporating GEV distribution into the training of a DNN.
2. We propose a reformulation of the GEV constraints to ensure they can be enforced using activation functions in the DNN.
3. We introduce a model bias offset mechanism to ensure that the DNN output preserves the regularity conditions of the GEV parameters despite its random initialization.
4. We perform extensive experiments on both real-world and synthetic data to demonstrate the effectiveness of DeepExtrema compared to other baseline methods.

2 Preliminaries

2.1 Problem Statement

Let \(z_1, z_2, \ldots, z_T\) be a time series of length \(T\). Assume the time series is partitioned into a set of time windows, where each window \([t - \alpha, t + \beta]\) contains a sequence of predictors, \(x_t = (z_{t-\alpha}, z_{t-\alpha+1}, \ldots, z_t)\), and target, \(y_t = (z_{t+1}, z_{t+2}, \ldots, z_{t+\beta})\). Note that \(\beta\) is known as the forecast horizon of the prediction. For each time window, let \(\hat{y}_t = \max_{r \in \{1, \ldots, \beta\}} z_{t+r}\) be the block maxima of the target variable at time \(t\). Our time series forecasting task is to estimate the block maxima, \(\hat{y}_t\), as well as its upper and lower quantile estimates, \(\hat{q}_L\) and \(\hat{q}_U\), of a future time window based on current and past data, \(x_t\).

2.2 Generalized Extreme Value Distribution

The GEV distribution governs the distribution of block maxima in a given window. Let \(Y = \max\{z_1, z_2, \ldots, z_t\}\). If there exist sequences of constants \(a_t > 0\) and \(b_t\) such that

\[
Pr(Y - b_t) / a_t \leq y \rightarrow G(y) \quad \text{as} \quad t \rightarrow \infty
\]

for a non-degenerate distribution \(G\), then the cumulative distribution function \(G\) belongs to a family of GEV distribution of the form [Coles et al., 2001]:

\[
G(y) = \exp \left\{ - \left[ 1 + \xi (\frac{y - \mu}{\sigma}) \right]^{1/\xi} \right\}
\]

(1)

The GEV distribution is characterized by the following parameters: \(\mu\) (location), \(\sigma\) (scale), and \(\xi\) (shape). The expected value of the distribution is given by

\[
y_{\text{mean}} = \mu + \frac{\sigma}{\xi} \left[ \Gamma(1 - \xi) - 1 \right]
\]

(2)

where \(\Gamma(x)\) denotes the gamma function of a variable \(x > 0\). Thus, \(y_{\text{mean}}\) is only well-defined for \(\xi < 1\). Furthermore, the \(p^{th}\) quantile of the GEV distribution, \(y_p\), can be calculated as follows:

\[
y_p = \mu + \frac{\sigma}{\xi} \left[ (-\log p)^{-\xi} - 1 \right]
\]

(3)

Given \(n\) independent block maxima values, \(\{y_1, y_2, \ldots, y_n\}\), with the distribution function given by Equation (1) and assuming \(\xi \neq 0\), its log-likelihood function is given by:

\[
\ell_{\text{GEV}}(\mu, \sigma, \xi) = -n \log \sigma - \left( \frac{1}{\xi} + 1 \right) \sum_{i=1}^{n} \log(1 + \xi \frac{y_i - \mu}{\sigma})
\]

\[
- \sum_{i=1}^{n} (1 + \xi \frac{y_i - \mu}{\sigma})^{-1/\xi}
\]

(4)

The GEV parameters \((\mu, \sigma, \xi)\) can be estimated using the maximum likelihood (ML) approach by maximizing (4) subject to the following positivity constraints:

\[
\sigma > 0 \quad \text{and} \quad \forall i: 1 + \xi \frac{y_i - \mu}{\sigma} > 0
\]

(5)

In addition to the above positivity constraints, the shape parameter \(\xi\) must be within certain range of values in order
for the ML estimators to exist and have regular asymptotic properties [Coles et al., 2001]. Specifically, the ML estimators have regular asymptotic properties as long as $\xi > -0.5$. Otherwise, if $-1 < \xi < -0.5$, then the ML estimators may exist but will not have regular asymptotic properties. Finally, the ML estimators do not exist if $\xi < -1$ [Smith, 1985].

3 Proposed Framework: DeepExtrema

This section presents the proposed DeepExtrema framework for predicting the block maxima of a given time window. The predicted block maxima $\hat{y}$ follows a GEV distribution, whose parameters are conditioned on observations of the predictors $x$. Figure 2 provides an overview of the DeepExtrema architecture. Given the input predictors $x$, the framework uses a stacked LSTM network to learn a representation of the time series. The LSTM will output a latent representation, which will be used by a fully connected layer to generate the GEV parameters:

$$
(\mu, \sigma, \xi_u, \xi_l) = LSTM(x)
$$

(6)

where $\mu$, $\sigma$, and $\xi$’s are the location, shape, and scale parameters of the GEV distribution. Note that $\xi_u$ and $\xi_l$ are the estimated parameters due to reformulation of the GEV constraints, which will be described in the next subsection.

The proposed Model Bias Offset (MBO) component performs bias correction on the estimated GEV parameters to ensure that the LSTM outputs preserve the regularity conditions of the GEV parameters irrespective of how the network was initialized. The GEV parameters are subsequently provided to a fully connected layer to obtain point estimates of the block maxima, which include its expected value $\hat{\mu}$ as well as upper and lower quantiles, $\hat{y}^{U}$ and $\hat{y}^{L}$, using the equations given in (2) and (3), respectively. The GEV parameters are then used to compute the negative log-likelihood of the estimated GEV distribution, which will be combined with the root-mean-square error (RMSE) of the predicted block maxima to determine the overall loss function. Details of the different components are described in the subsections below.

3.1 GEV Parameter Estimation

Let $D = \{(x_i, y_i)\}_{i=1}^n$ be a set of training examples, where each $x_i$ denotes the predictor time series and $y_i$ is the corresponding block maxima for time window $i$. A naïve approach is to assume that the GEV parameters $(\mu, \sigma, \xi)$ are constants for all time windows. This can be done by fitting a global GEV distribution to the set of block maxima values $y_i$’s using the maximum likelihood approach given in (4). Instead of using a global GEV distribution with fixed parameters, our goal is to learn the parameters $(\mu_i, \sigma_i, \xi_i)$ of each window $i$ using the predictors $x_i$. The added flexibility enables the model to improve the accuracy of its block maxima prediction, especially for non-stationary time series.

The estimated GEV parameters generated by the LSTM must satisfy the two positivity constraints given by the inequalities in (5). While the first positivity constraint on $\sigma_i$ is straightforward to enforce, maintaining the second one is harder as it involves a nonlinear relationship between $y_i$ and the estimated GEV parameters, $\xi_i$, $\mu_i$, and $\sigma_i$. The GEV parameters may vary from one input $x_i$ to another, and thus, learning them from the limited training examples is a challenge. Worse still, some of the estimated GEV parameters could be erroneous, especially at the initial rounds of the training epochs, making it difficult to satisfy the constraints throughout the learning process.

To address these challenges, we propose a reformulation of the second constraint in (5). This allows the training process to proceed even though the second constraint in (5) has yet to be satisfied especially in the early rounds of the training epochs. Specifically, we relax the hard constraint by adding a small tolerance factor, $\tau > 0$, as follows:

$$
\forall i : 1 + \frac{\xi}{\sigma}(y_i - \mu) + \tau \geq 0.
$$

(7)

The preceding soft constraint allows for minor violations of the second constraint in (5) as long as $1 + \frac{\xi}{\sigma}(y_i - \mu) > -\tau$ for all time windows $i$. Furthermore, to ensure that the inequality holds for all $y_i$’s, we reformulate the constraint in (7) in terms of $y_{\min} = \min_i y_i$ and $y_{\max} = \max_i y_i$ as follows:

**Theorem 1.** Assuming $\xi \neq 0$, the soft constraint in (7) can be reformulated into the following bounds on $\xi$:

$$
-\frac{\sigma}{y_{\max} - \mu} (1 + \tau) \leq \xi \leq \frac{\sigma}{\mu - y_{\min}} (1 + \tau)
$$

(8)

where $\tau$ is the tolerance on the constraint in 5.

**Proof.** For the lower bound on $\xi$, set $y_i$ to be $y_{\max}$ in (7):

$$
1 + \frac{\xi}{\sigma}(y_{\max} - \mu) + \tau \geq 0 \quad \Rightarrow \quad \frac{\xi}{\sigma}(y_{\max} - \mu) \geq - (1 + \tau)
$$

$$
\Rightarrow \quad \xi \geq -\frac{\sigma}{(y_{\max} - \mu)} (1 + \tau)
$$

To obtain the upper bound on $\xi$, set $y_i$ to be $y_{\min}$ in (7):

$$
1 + \frac{\xi}{\sigma}(y_{\min} - \mu) + \tau \geq 0 \quad \Rightarrow \quad \frac{\xi}{\sigma}(\mu - y_{\min}) \leq (1 + \tau)
$$

$$
\Rightarrow \quad \xi \leq \frac{\sigma}{(\mu - y_{\min})} (1 + \tau)
$$

$\square$
Following Theorem 1, the upper and lower bound constraints on $\xi$ in (8) can be restated as follows:

$$\frac{\sigma}{\mu - y_{\text{min}}} (1 + \tau) - \xi \geq 0$$

$$\xi + \frac{\sigma}{y_{\text{max}} - \mu} (1 + \tau) \geq 0 \quad (9)$$

The reformulation imposes lower and upper bounds on $\xi$, which can be used to re-parameterize the second constraint in (5). Next, we describe how the reformulated constraints in (9) can be enforced by DeepExtrema in a DNN.

Given an input $x_i$, DeepExtrema will generate the following four outputs: $\mu_i, P_{1i}, P_{2i},$ and $P_{3i}$. A softplus activation function, $\text{softplus}(x) = \log (1 + \exp (x))$, which is a smooth approximation to the ReLU function, is used to enforce the non-negativity constraints associated with the GEV parameters. The scale parameter $\sigma_i$ can be computed using the softplus activation function on $P_{1i}$ as follows:

$$\sigma_i = \text{softplus}(P_{1i}) \quad (10)$$

This ensures the constraint $\sigma_i > 0$ is met. The lower and upper bound constraints on $\xi_i$ given by the inequalities in (9) are enforced using the softplus function on $P_{2i}$ and $P_{3i}$:

$$\frac{\sigma_i}{\mu_i - y_{\text{min}}} (1 + \tau) - \xi_{u,i} = \text{softplus}(P_{2i})$$

$$\frac{\sigma_i}{y_{\text{max}} - \mu_i} (1 + \tau) + \xi_{l,i} = \text{softplus}(P_{3i}) \quad (11)$$

By re-arranging the above equation, we obtain

$$\xi_{u,i} = \frac{\sigma_i}{\mu_i - y_{\text{min}}} (1 + \tau) - \text{softplus}(P_{2i})$$

$$\xi_{l,i} = \text{softplus}(P_{3i}) - \frac{\sigma_i}{y_{\text{max}} - \mu_i} (1 + \tau) \quad (12)$$

DeepExtrema computes the upper and lower bounds on $\xi_i$ using the formulas in (12). During training, it will minimize the distance between $\xi_{u,i}$ and $\xi_{l,i}$ and will use the value of $\xi_{u,i}$ as the estimate for $\xi_i$. Note that the two $\xi_i$’s converge rapidly to a single value after a small number of training epochs.

3.2 Model Bias Offset (MBO)

Although the constraint reformulation approach described in the previous subsection ensures that the DNN outputs will satisfy the GEV constraints, the random initialization of the network can produce estimates of $\xi$ that violate the regularity conditions described in Section 2.2. Specifically, the ML-estimated distribution may not have the asymptotic GEV distribution when $\xi < -0.5$ while its conditional mean is not well-defined when $\xi > 1$. Additionally, the estimated location parameter $\mu$ may not fall within the desired range between $y_{\text{min}}$ and $y_{\text{max}}$ when the DNN is randomly initialized. Thus, without proper initialization, the DNN will struggle to converge to a good solution and produce acceptable values of the GEV parameters.

One way to address this challenge is to repeat the random initialization of the DNN until a reasonable set of initial GEV parameters, i.e., $y_{\text{min}} \leq \mu \leq y_{\text{max}}$ and $-0.5 < \xi < 1$, is found. However, this approach is infeasible given the size of the parameter space of the DNN. A better strategy is to control the initial output of the neural network in order to produce an acceptable set of GEV parameters, $(\mu, \sigma, \xi)$, during initialization. Unfortunately, controlling the initial output of a neural network is difficult given its complex architecture.

We introduce a simple but effective technique called Model Bias Offset (MBO) to address this challenge. The key insight here is to view the GEV parameters as a biased output due to the random initialization of the DNN and then perform bias correction to alleviate the effect of the initialization. To do this, let $\mu_{\text{desired}}, \sigma_{\text{desired}},$ and $\xi_{\text{desired}}$ be an acceptable set of initial GEV parameters. The values of these initial parameters must satisfy the regularity conditions $-0.5 < \xi_{\text{desired}} < 1$, $\sigma_{\text{desired}} > 0$, and $y_{\text{min}} \leq \mu_{\text{desired}} \leq y_{\text{max}}$. This can be done by randomly choosing a value from the preceding range of acceptable values, or more intelligently, using the GEV parameters estimated from a global GEV distribution fitted to the block maxima $y_i$’s in the training data via the ML approach given in (4), without considering the input predictors (see the discussion at the beginning of Section 3.1). We find that the latter strategy works well in practice as it can lead to faster convergence especially when the global GEV parameters are close to the final values after training.

When the DNN is randomly initialized, let $\mu_0, \sigma_0, \xi_{u,0},$ and $\xi_{l,0}$ be the initial DNN output for the GEV parameters. These initial outputs may not necessarily fall within their respective range of acceptable values. We consider the difference between the initial DNN output and the desired GEV parameters as a model bias due to the random initialization:

$$\mu_{\text{bias}} = \mu_0 - \mu_{\text{desired}}$$

$$\sigma_{\text{bias}} = \sigma_0 - \sigma_{\text{desired}}$$

$$\xi_{u,\text{bias}} = \xi_{u,0} - \xi_{u,\text{desired}}$$

$$\xi_{l,\text{bias}} = \xi_{l,0} - \xi_{l,\text{desired}} \quad (13)$$

The model bias terms in (14) can be computed during the initial forward pass of the algorithm. The gradient calculation and back-propagation are disabled during this step to prevent the DNN from computing the loss and updating its weight with the unacceptable GEV parameters. After the initial iteration, the gradient calculation will be enabled and the bias...
terms will be subtracted from the DNN estimate of the GEV parameters in all subsequent iterations $t$:

\[
\begin{align*}
\mu_t &\rightarrow \mu_t - \mu_{\text{bias}} \\
\sigma_t &\rightarrow \sigma_t - \sigma_{\text{bias}} \\
\xi_{u,t} &\rightarrow \xi_{u,t} - \xi_{u,\text{bias}} \\
\xi_{l,t} &\rightarrow \xi_{l,t} - \xi_{l,\text{bias}} \\
\end{align*}
\] (14)

Note that, when $\mu_t$ is set to $\mu_0$, then the debiased output $\mu_t - \mu_{\text{bias}}$ will be equal to $\mu_{\text{desired}}$. By debiasing the output of the DNN in this way, we guarantee that the initial GEV parameters satisfy the GEV regularity conditions.

3.3 Block Maxima Prediction

Given an input $x_i$, the DNN will estimate the GEV parameters needed to compute the block maxima $\hat{y}_i$, along with its upper and lower quantiles, $\hat{y}_{U,i}$ and $\hat{y}_{L,i}$, respectively. The quantiles are estimated using the formula given in (3). The GEV parameters are provided as input to a fully connected network (FCN) to generate the block maxima prediction, $\hat{y}_i$.

DeepExtrema employs a combination of the negative log-likelihood function ($-\ell_{\text{GEV}}(\mu, \sigma, \xi)$) of the GEV distribution and a least-square loss function to train the model. This enables the framework to simultaneously learn the GEV parameters and make accurate block maxima predictions. The loss function to be minimized by DeepExtrema is:

\[
\mathcal{L} = \lambda_1 \hat{\mathcal{L}} + (1 - \lambda_1) \sum_{i=1}^{n} (y_i - \hat{y}_i)^2
\] (15)

where $\hat{\mathcal{L}} = -\lambda_2 \ell_{\text{GEV}}(\mu, \sigma, \xi) + (1 - \lambda_2) \sum_{i=1}^{n} (\xi_{U,i} - \xi_{L,i})^2$ is the regularized GEV loss. The first term in $\hat{\mathcal{L}}$ corresponds to the negative log-likelihood function given in Equation (4) while the second term minimizes the difference between the upper and lower bound estimates of $\xi$. The loss function $\mathcal{L}$ combines the regularized GEV loss ($\hat{\mathcal{L}}$) with the least-square loss. Here, $\lambda_1$ and $\lambda_2$ are hyperparameters to manage the trade-off between different factors of the loss function.

4 Experimental Evaluation

This section presents our experimental results comparing DeepExtrema against the various baseline methods. The code and datasets are available at https://github.com/galib19/DeepExtrema-IJCAI22-.

4.1 Data

Synthetic Data

As the ground truth GEV parameters are often unknown, we have created a synthetic dataset to assess our method’s ability to correctly infer the GEV parameters. The data is generated assuming the GEV parameters are functions of some input predictors $x \in \mathbb{R}^6$. We first generate $x$ by random sampling from a uniform distribution. We then assume a non-linear mapping from $x$ to the GEV parameters $\mu$, $\sigma$, and $\xi$, via the following nonlinear equations:

\[
\begin{align*}
\mu(x) &= w_{\mu}^T (\exp(x) + x) \\
\sigma(x) &= w_{\sigma}^T (\exp(x) + x) \\
\xi(x) &= w_{\xi}^T (\exp(x) + x) \\
\end{align*}
\] (16)

where $w_{\mu}$, $w_{\sigma}$, and $w_{\xi}$ are generated from a standard normal distribution. Using the generated $\mu$, $\sigma$, and $\xi$ parameters, we then randomly sample $y$ from the GEV distribution governed by the GEV parameters. Here, $y$ denotes the block maxima as it is generated from a GEV distribution. We created 8,192 block maxima values for our synthetic data.

Real World Data

We consider the following 3 datasets for our experiments.

Hurricane: This corresponds to tropical cyclone intensity data obtained from the HURDAT2 database [Landsea and Franklin, 2013]. There are altogether 3,111 hurricanes spanning the period between 1851 and 2019. For each hurricane, wind speeds (intensities) were reported at every 6-hour interval. We consider only hurricanes that have at least 24-time steps at minimum for our experiments. For each hurricane, we have created non-overlapping time windows of length 24 time steps (6 days). We use the first 16 time steps (4 days) in the window as the predictor variables and the block maxima of the last 8 time steps (2 days) as the target variable.

Solar: This corresponds to half-hourly energy use (kWh) for 55 families over the course of 284 days from Ausgrid database [Ratnam et al., 2017]. We preprocess the data by creating non-overlapping time windows of length 192 time steps (4 days). We use the first 144 time steps (3 days) in the window as the predictor variables and the block maxima of the last 48 time steps (1 day) as the target variable.

Weather: We have used a weather dataset from the Kaggle competition [Muthukumar, 2017]. The data is based on hourly temperature data for a city over a ten-year period. We use the first 16 time steps (16 hours) in the window as the predictor variables and the block maxima of the last 8 time steps (8 hours) as the target variable.

4.2 Experimental Setup

For evaluation purposes, we split the data into separate training, validation, testing with a ratio of 7:2:1. The data is standardized to have zero mean and unit variance. We compare DeepExtrema against the following baseline methods: (1) Persistence, which uses the block maxima value from the previous time step as its predicted value, (2) fully-connected network (FCN), (3) LSTM, (4) Transformer, (5) DeepPIPE [Wang et al., 2020], and (6) EVL [Ding et al., 2019]. We will use the following metrics to evaluate the performance of the methods: (1) Root mean squared error (RMSE) and correlation between the predicted and ground truth block maxima and (2) Negative log-likelihood (for synthetic data). Finally, hyperparameter tuning is performed by assessing the model performance on the validation set. The hyperparameters of the baseline and the proposed methods are selected using Ray Tune, a tuning framework with ASHA (asynchronous successive halving algorithm) scheduler for early stopping.

4.3 Experimental Results

Results On Synthetic Data

In this experiment, we have compared the performance of DeepExtrema against using a single (global) GEV parameter to fit the data. Based on the experiments, DeepExtrema achieves a substantially lower negative log-likelihood of 4410
than the global GEV estimate, which has a negative log-likelihood of 4745. This result supports the assumption that each block maxima comes from different GEV distributions rather than a single (global) GEV distribution.

### Results On Real World Data

Evaluation on real-world data shows that DeepExtrema outperforms other baseline methods used for comparison for all data sets (see Table 1). For RMSE, DeepExtrema generates lower RMSE compared to all the baselines on all 3 datasets, whereas for correlation, DeepExtrema outperforms the baselines on 2 of the 3 datasets.

To demonstrate how well the model predicts the extreme values, Figure 4 shows a scatter plot of the actual versus predicted values generated by DeepExtrema on the test set of the hurricane intensity data. The results suggest that DeepExtrema can accurately predict the hurricane intensities for a wide range of values, especially those below 140 knots. DeepExtrema also does a better job at predicting the high intensity hurricanes compared to EVL [Ding et al., 2019], as illustrated in Figure 5. Figure 6 shows the 90% confidence interval of the predictions. Apart from the point and quantile estimations, DeepExtrema can also estimate the GEV parameter values for each hurricane.

### Ablation Studies

The hyperparameter $\lambda_1$ in the objective function of DeepExtrema denotes the trade-off between regularized GEV loss and RMSE loss. Experimental results show that the RMSE of block maxima prediction decreases when $\lambda_1$ increases (see Table 2). This validates the importance of incorporating GEV theory to improve the accuracy of block maxima estimation instead of using the mean squared loss alone.

### 5 Conclusion

This paper presents a novel deep learning framework called DeepExtrema that combines extreme value theory with deep learning to address the challenges of predicting extremes in time series. We offer a reformulation and reparameterization technique for satisfying constraints and a model bias offset technique for proper model initialization. We evaluated our framework on synthetic and real-world data and showed its effectiveness. For future work, we plan to extend the formulation to enable more complex deep learning architectures such as attention mechanism. Furthermore, the system will be expanded to model spatiotemporal extremes.
